PONTOCAINE HYDROCHLORIDE in OPHTHALMOLOGY and RHINOLARYNGOLOGY

Dependable anesthesia of the mucous membranes is readily obtained by the topical application of Pontocaine Hydrochloride. This widely used agent acts quickly, penetrates deeply, and gives prolonged anesthesia. A variety of operative and non-operative procedures on the eye, nose and throat may be successfully carried out with small quantities of relatively weak solutions.

HOW SUPPLIED: For surface anesthesia in ophthalmology: 0.5 per cent solution in bottles of $\frac{1}{2}$ oz. and 2 oz.

For surface anesthesia in rhinolaryngology: 2 per cent solution in bottles of 1 oz. and 4 oz.

Analgesic power

Demerol hydrochloride ranks between morphine and codeine in analgesic power. Furthermore, it possesses marked spasmolytic and mild sedative action. It causes less nausea and vomiting and less urinary retention than morphine, and no constipation. The danger of respiratory depression is also greatly reduced with Demerol hydrochloride. Warning: May be habit forming. Ampuls of 2 cc. (100 mg.) and tablets of 50 mg. Narcotic blank required.

Nasal Allergy

Two or three drops of Pontocaine Neo-Synephrine 0.25% Solution in each nostril keep the nasal passages open and comfortable in allergic rhinitis and sinusitis for several hours. Pontocaine Neo-Synephrine remains effective on repeated use and is essentially free from systemic side effects on the heart and central nervous system. It is also used in the eye for conjunctival irritation: 1 or 2 drops into the lower conjunctival sac every three or four hours. Bottles of 30 cc. (1 fl. oz.).

*Penetrating prolonged
action*

TOPICAL ANESTHESIA IN OPHTHALMOLOGY and RHINOLARYNGOLOGY

Dependable anesthesia of the mucous membranes is readily obtained by the topical application of Pontocaine hydrochloride. This widely used agent acts quickly, penetrates deeply, and gives prolonged anesthesia. A variety of operative and nonoperative procedures on the eye, nose and throat may be successfully carried out with small quantities of relatively weak solutions.

HOW SUPPLIED: For surface anesthesia in ophthalmology:
0.5 per cent solution in bottles of ½ oz. and 2 oz.

For surface anesthesia in rhinolaryngology: 2 per cent
solution in bottles of 1 oz. and 4 oz.

INDEX

Preoperative Calm and *Postoperative* Comfort

PREOPERATIVE apprehension and excitation are readily reduced with Demerol, the potent analgesic, spasmolytic and sedative. In addition to psychic sedation, Demerol facilitates the induction of anesthesia, reduces the amount of anesthetic required, and effectively dries secretions. Compared with morphine, it entails practically no risk of respiratory depression and causes considerably less nausea and vomiting.

POSTOPERATIVE comfort is reliably obtained without interference with the cough reflex or bowel movements and with little danger of urinary retention. Patients in all age groups, regardless of the type of surgery or severity of pain, respond favorably to the drug. Ampuls (2 cc., 100 mg.); vials (30 cc., 50 mg./cc.); tablets (50 mg.); powder (15 Gm.) for prescription purposes. Council Accepted

PROLIFERATION OF THE EPITHELIUM OF THE LENS*

BERNARD SAMUELS, M.D.

New York

In the early days of the present century, it was decided that ectoderm and mesoderm are different and independent tissues and that the one cannot produce the other. This decision was arrived at largely from experiments made on the cornea. The cornea was employed, first, because it has relatively few cells of its own and, second, because the corneal corpuscles are characteristic and can be readily differentiated from cells that invade the cornea as a result of infection or trauma. The lens was not used in the early experiments because of its inaccessibility within the globe and the impossibility of reaching it without damaging nearby structures. If it had been available, it would have been evident at that time that a strict differentiation between ectoderm and mesoderm cannot always be made. It is possible for the epithelial cells of the lens, when irritated, to lay down a tissue, the anterior-subcapsular cataract, that has more of the

physical qualities of mesoderm than of ectoderm. In later experiments as an object of embryologic investigation, the lens proved to be valuable in revealing the influence of the presence of one organ on the development of another, notably the effect of the retina on the development of the lens. In the cultivation of living tissue the epithelium of the lens has been employed with informative results.

Since the discovery that the lens is the site of cataract and that by its removal blindness can be cured, interest in the anatomy, pathology, physiology, and chemistry of the lens has never ceased. The radical operation of intracapsular extraction has once more directed attention to the physiology of the lens, since after this procedure complications may arise that seem to be caused by the removal of every vestige of this organ. The iris loses its support and may become tremulous. The vitreous may prolapse into the anterior chamber, and the retina may be lacerated and detached by the tremulous vitreous. The pupil may be drawn up as a consequence of complete

aphakia. In the extracapsular operation, the preservation of the equatorial zone of the lens has the advantage of providing a cushion known for generations as Soemmerring's crystalline swelling, on which the ciliary zone of the iris may rest. It would seem, therefore, that the lens has functions other than those having to do solely with vision.

SOEMMERRING'S CRYSTALLINE SWELLING

Much information concerning the proliferative powers of the lenticular epi-

thelium has been gained from examinations of the lens after the capsule has been opened, and a number of practical problems have been solved. It is known that Soemmerring's crystalline swelling consists of more than left-over lens matter. Within the sealed ring, there takes place a proliferation of the germinal cells, and the younger the lens the more active the process and the more distended and larger the ring (fig. 1). In doing a discission, it is often surprising, if the ring is opened, how great an amount of lens matter escapes. To guard against a secondary membrane in cases of extracapsular extraction, a large piece of the anterior capsule is excised so that no subcapsular cells are left to multiply and change into opaque fibers or to form so-

called pearls of Elschnig (fig. 2, color plate). Unfortunately, after a cataract operation, if the eye remains irritable for a long period, exudative cells from the uvea may be deposited on the posterior capsule of the lens or on the anterior limiting layer of the vitreous. The singular phenomenon is that these cells also produce a connective-tissuelike membrane without there being the least sign that any element from the walls of a blood vessel took part in the process.

MATERIAL

The present paper has for its chief purpose the summarizing of the proliferation of the epithelial cells of the lens in 185 cases of nontraumatic cataract. The cases were arranged in the following manner according to what was believed to have been the main factor in the production of the cataract:

	Cases
1. Ulcers of the cornea	18
2. Corneal scars	35
3. Spontaneous iritis	20
4. Spontaneous detachment of the retina..	23
5. Intraocular tumors	58
6. Glaucoma	31

The six groups have been the subject of as many publications.¹⁻⁶ Scattered through these articles will be found much that is mentioned here, as well as many of the illustrations. Cataracts with a ruptured capsule were excluded from this long and varied list because the moment a capsule is opened, cells may enter from the uvea, as mentioned, and produce a tissue of their own, rendering the picture no longer one of pure epithelial proliferation.

IMPERMEABILITY OF THE LENS CAPSULE

Since this paper concerns exclusively the proliferation of the lenticular epithelium, the question arises as to whether or not the lens capsule is pervious to cells from without. It is certain that, in very severe inflammation, pus cells may pass

Figs. 3 and 4 (Samuels). Fig. 3, Pus cells near the anterior pole of the lens, lying between the subcapsular epithelium and the normal cortical substance. Apparently the capsule was intact. Fig. 4, Phagocytelike cells scattered along the posterior capsule. No hole was found in the capsule.

through the other two glass membranes; namely, Descemet's membrane and the lamina vitrea of the choroid. Leukocytes seem to be able to penetrate Descemet's membrane from either the corneal or the chamber side. The lamina vitrea of the choroid seems to be less permeable than Descemet's membrane. It is a common picture in panophthalmitis to see a focus of pus cells in the choroid congregated against the lamina vitrea detaching the pigment epithelium by fluid but not by pus cells.

There were two cases in which the origin of the cells was doubtful:

Case 1. Leukocytes beneath the capsule. The anterior chamber was filled with pus. A row of leukocytes had insinuated itself between the partially necrotic epithelium and the normal cortical substance (fig. 3). The capsule showed no sign of collapse as it would have done had it been perforated, allowing the escape of lens matter. In the absence of serial sections, the possibility of a hole in the capsule could not be excluded. My belief in the impermeability of the lens capsule to cellular elements remains unchanged.

Case 2. Phagocytes beneath the capsule. A retinoblastoma had filled an infant's eye, causing buphthalmos. The lens substance was liquefied. The remarkable feature was the presence of large, round hydropic cells straggling along the inner surface of the posterior capsule (fig. 4). Each cell had a small oblong nucleus and a foamlike protoplasm that gave it the

appearance of a phagocyte that had taken up lipoid material which is certainly not lacking in the cataractous lens. There was a possibility that these were mononuclear cells which had traversed the capsule. On the other hand, they might have been cells of the capsular epithelium which had migrated posteriorly and changed in the liquefied medium.

In this connection, the lens in one of the cases of malignant melanoma showed how greatly the subcapsular cells may alter. A small, anterior-subcapsular cataract had formed and, nearby, some of the

Fig. 5 (Samuels). Transformation of the low-cuboidal subcapsular epithelium into large, round hydropic cells, arranged in the form of a bunch of grapes suspended in the fluid cortical substance.

cells had desquamated. At another spot in the pupillary area, the cells had proliferated and arranged themselves in the form of a bunch of grapes which was suspended from the capsule into the fluid cortex (fig. 5). There was no doubt that they were derivatives of the lens epithelium. They were large, round, and hydropic, and their nuclei resembled the nuclei

mon site for the multiplication of the subcapsular cells and here they attained their highest degree of growth (fig. 6, color plate). Probably these cells have a special inclination to proliferate and, certainly in inflammation of the cornea, they are more exposed to direct irritation than the cells under the iris.

b. Excentric Cataract. The cataract

Fig. 7 (Samuels). L points to the lens and C to one of the anterior-subcapsular cataracts. The lens is dislocated into the anterior chamber and is turned around.

of the cells described above. The principal difference was that these cells had not taken up extraneous matter.

PROLIFERATION OF THE LENTICULAR EPITHELIUM

The proliferation was classified as follows: A. proliferation of the anterior-capsular cells; B. proliferation of the germinal cells; and, C. unusual findings.

A. PROLIFERATION OF THE ANTERIOR-CAPSULAR EPITHELIUM (SUBCAPSULAR CATARACT)

1. Localization of Subcapsular Cataract

a. Central Cataracts. The center of the pupil was found to be the most com-

mon site for the multiplication of the subcapsular cells and here they attained their highest degree of growth (fig. 6, color plate). Probably these cells have a special inclination to proliferate and, certainly in inflammation of the cornea, they are more exposed to direct irritation than the cells under the iris.

b. Excentric Cataract. The cataract was not invariably composed of one focus of proliferation. For example, in one lens there were two separate cataracts at a distance from the center (fig. 7). Cataracts at the equator were encountered usually as an extension of an anterior cataract. In a case of blindness from metastatic ophthalmia in a boy, aged six years, a cataract grew on the posterior capsule. In the recessus hyaloideo-capsularis there was a large focus of inflammatory cells. Epithelial cells coated the posterior capsule. Adjacent to the focus of cells in the recessus, the epithelial cells laid down a fibrous membrane—a true posterior-subcapsular cataract of ectodermal origin (fig. 8). The transplanted cells had not lost their power

Figs. 8 to 15 (Samuels). Fig. 8. At P there is a mass of exudative cells showing a giant cell to the left. The overlying epithelial cells reacted to the irritation by laying down a connective-tissuelike membrane. Fig. 9. to lay down a connective-tissuelike substance.

2. Rapid Proliferation

Case 1. The most rapidly grown cataracts were seen in cases of corneal ulcers, especially those with a posterior abscess about to rupture. Thus it was in a case of lagophthalmic ulcer in the cornea of a 21-year-old man (fig. 9). Twelve days after the onset, the eye was enucleated because the ulcer had perforated, causing the iris to prolapse. In this brief period, a highly elevated and sharply defined anterior-polar cataract developed, showing already a tendency to contract.

In a second case, the eye of a boy, aged 12 years, was removed three weeks after the onset of a perforated serpiginous ulcer. Here, instead of one patch of proliferation, there were three separate cataracts, each detaching the anterior capsule. The cells bordering the proliferated areas were scanty and exceedingly flat (fig. 10). They were apparently mature cells that had flattened in order to creep along the capsule and replace cells that had disappeared. It is known that newly formed epithelial cells have a directed growth and an inherent tendency to move toward a certain place (positive chemotaxis). It is likely that even fully mature cells may change their shape and show a similar phenomenon of motion. In this instance, the early stage of the formation of an anterior-polar cataract was revealed. The cells were small, compactly disposed, and rich in protoplasm. As yet no intercellular substance had been laid down.

In a third case, one of sympathetic ophthalmia, over-rapid proliferation was shown by the presence of many mitotic figures which resembled the atypical star figures seen in malignant growths (fig. 11). In the entire series; this case and

another were the only ones in which mitotic figures were encountered.

3. Shape and Consistency of Subcapsular Cataracts

Three types of anterior-polar cataract were differentiated in this material: (a) the widespread type with an undulating anterior surface (fig. 12); (b) the pyramidal type projecting abruptly forward (fig. 13); (c) the thin, fibrous type with sharp wrinkles in the capsule (fig. 14). This classification was made according to the contours of the anterior surface. Posteriorly, the outline was always concave, conforming to the outline of the anterior surface of the nucleus. Apparently, the growing cells find it easier to detach the capsule than to indent the nucleus. In its fully developed state, an anterior-polar cataract shows few nuclei and a very abundant intercellular substance (fig. 15). It is indeed an "epithelial connective tissue." It may even have a fine lamination. The older the cataract the more homogeneous it is. Its toughness becomes manifest when attempts are made to tear it. Eventually, it may become calcified just like any ordinary connective-tissue scar. In the matter of staining, it differs from connective tissue in that it takes a yellow instead of a red stain. Chemically, it has the property of the capsule.

4. Reaction to Irritation (Pyramidal Type of Cataract)

The pyramidal cataracts were usually associated with corneal ulcers, especially with those about to rupture. They were the result of short but concentrated exposure to toxins. Simultaneously with the rupture of the cornea come the release of the toxins from the anterior chamber and the arrest of the growth. By contraction, the isolated mass of proliferation

elevates itself and detaches the capsule. However, it affects but slightly the lens nucleus from which it separates easily, merely sliding on it. It may remain of the same size and whiteness throughout life.

An example of the effect of local irritation was a case of serpiginous ulcer in which a wide perforation of the cornea brought good drainage to the anterior chamber (fig. 16). At one point on the capsule, the cornea, with the advancing border of the ulcer, lay in direct contact with the lens, and proliferation of the subcapsular cells was confined to this point. The entire pupillary area of the lens was covered by a coagulum of pus and blood and, under this, the subcapsular cells were well preserved. In the study of the corneal ulcer cases, it was noted that a hypopyon may have the benign effect of forming a curtain that protects the subcapsular cells from the toxins eliminated by the bacteria in the cornea.

5. Reaction to General Irritation (Widespread Type of Cataract)

Extensive proliferation, sometimes reaching beyond the pupillary area, was characteristic of the cases of spontaneous detachment of the retina. An unusually widespread cataract was found in a woman's eye, blind for 25 years due to long lasting toxins from the subretinal fluid (fig. 17). The most interesting point was its association with a similar connective-tissuelike formation at the ora serrata which had been laid down by the pigmented epithelium. A similar tissue may be found posteriorly on the choroid when the retina has been long detached. Occasionally this tissue of epithelial origin may be found in all three locations in the same eye. They are all believed to be the result of a low grade reaction to a prolonged but not virulent stimulus.

6. Basal Cells of Posterior Polar Cataract

In a number of cases, a single layer of more or less cuboidal cells outlined and separated the subcapsular cataract from the lens substance. Being very nuclear, the layer stood out by contrast against the overlying homogeneous cataract. Treacher Collins⁵ found that these

Fig. 16 (Samuels). The cornea has ruptured from a serpiginous ulcer, and the open space is filled with pus and blood. Two cataracts have formed, the larger one directly under the necrotic pupillary border of the iris over which is a posterior abscess in the cornea.

cells could secrete a glass membrane on the posterior surface of the cataract. In the specimens, the basal cells were found only in the late stages of the cataract (fig. 18). They never spread into the cataract and seemed never to have taken part in its formation. Evidently the subcapsular epithelium has a particular urge to wall off and isolate an abnormal mass.

7. Spread of Subcapsular Epithelium Posteriorly

As long as the whorl of the germinal zone in which the epithelial system ends at the equator is preserved, it is not possible for the anterior capsular cells to proliferate posteriorly. However, when the germinal cells have disappeared or have fallen away from the capsule, the anterior cells may then take their place and grow

Figs. 17 to 22 (Samuels). Fig. 17. Anterior polar cataract caused by toxins from an old detachment of the retina. Fig. 18. Cystic space lined by flat cells in the midst of an old anterior subcapsular cataract. Fig. 19. The entire capsule is lined by a row of epithelial cells. The thicker capsule to the right is the anterior capsule. Fig. 20. The iris has become necrotic from the sudden cutting off of the circulation in acute glaucoma. Necrosis of the iris followed, causing also necrosis of the underlying subcapsular cells. Fig. 21. Nodules of a homogenous material (drusen) laid down by the subcapsular epithelium under the protection of the iris in a thwarted attempt to cover the denuded pupillary area to the left. Fig. 22. Pu points to the pupillary area and C to the capsule. I points to the iris, P to the pigment layer, and B to broken down pigmented cells. At N, there are desquamated epithelial cells under the capsule, and at G there is a tuft of proliferated cells.

backward to line the posterior capsule in one continuous layer. The migration backward was usually found in association

with liquefaction of the entire cortical substance of the lens, in which condition the germinal zone no longer exists. This

was illustrated in a case of hydrophthalmos in which the substance was totally liquefied, the patient being only 22 years of age (fig. 19). The posterior capsule was lined by a single layer of epithelial cells, so that the two poles could be distinguished only by the difference in thickness of the capsules. In the group of cases of detached retinas, the proliferation backward was frequent as if the cells

pupillary border but being unable to proceed into the denuded area, drew back upon themselves and laid down a homogeneous mass of lenticular shape. Again, in one of the glaucoma cases, a sudden and complete blocking of the angle cut off the blood supply to the iris and caused it to become necrotic (fig. 22). In turn, toxins from the necrotic pupillary zone of the iris, where it touched the capsule,

Figs. 23 and 24 (Samuels). Fig. 23. Vesicular cells along the posterior capsule. C points to the protoplasm of a cell and S to a cystic space in one of the cells. Fig. 24. Distorted subcapsular epithelial cells.

had a purpose to protect the lens from toxins coming from that direction.

8. Proliferation to Repair Defects

Now and then in this long survey, the same lens showed both a stretch of necrosis and an attempt at repair by the adjoining cells (fig. 20). Among the causes of necrosis were toxins from a serpiginous ulcer, pressure of the lens against the cornea in glaucoma, toxins from a necrotic iris in touch with the capsule, and toxins from necrotic tumors. It became evident that it is a trait of the lenticular epithelium, like that of the corneal endothelium, to attempt to repair any defect in its continuity. Such an attempt was demonstrated in a case of lime burn of the cornea followed by a serpiginous ulcer (fig. 21). A purulent exudate filled the anterior chamber, causing the death of the central subcapsular cells. The adjoining cells, spared because they had been protected by the iris, multiplied at the

killed the underlying epithelium. At a distance toward the periphery, where the aqueous separated the iris from the lens capsule, the living cells attempted to repair the damage but, being thwarted, proliferated in the form of tufts of cells.

B. PROLIFERATION OF THE GERMINAL CELLS (VESICULAR CELLS)

In the process of developing flat and slender fibers from the germinal cells at the equator, the cells are pressed against a wall of preëxisting lens fibers. It is pressure that helps to mold the newly formed cells into fibers. In the cases of retinal detachment, since the lens was so frequently liquefied, making the pressure equal in all directions, it followed that it was in this group that vesicular cells were found most often and in greatest abundance (fig. 23). They are large bladderlike cells with a faintly staining nucleus and protoplasm enclosed in a sharply defined cell border. Occasionally they are very much elongated because, after

all, they are but misshapen lens fibers. Their favorite site was at the equator, but often they were located along the posterior capsule, less often anteriorly as if they had been pressed in either direction in the liquid cortex. In the process of disappearing, they lose their nuclei and frequently merge to form a large cystic

and took on a palisadelike arrangement due to traction exerted by the folded and detached capsule (fig. 24).

2. Drusen of the Capsule

In two cases, one in the group of spontaneous iritis and one in the group of intraocular tumors, the epithelium was

Figs 26 and 27 (Samuels). Fig. 26. Spherical body of epithelial elements floating in the liquid cortex. Fig. 27. Initial stage in the formation of an anterior polar cataract.

space, for they represent a phase in the development of a total cataract. They were found least often in glaucoma cases in which, as a rule, the lenses were the best preserved.

Metaplasia. Regarding metaplasia, the rapidity with which the epithelial cells changed their character, added to this property of contracting from the start (in one case 12 days), was astonishing (figs. 6 and 28). It was never certain that the anterior cells ever produced vesicular cells, nor was it certain that the germinal cells ever produced connective tissue. Whenever a cataract was found at the equator or posteriorly, it was considered to be the product of wandering anterior subcapsular cells.

C. UNUSUAL FINDINGS

1. Distortion of Cells by Traction

In another case in the group of corneal scars, the capsular cells lost their normal cuboidal shape, became elongated,

detached from the capsule by a homogeneous, roundish mass hugging the capsule and taking a similar stain (fig. 25, color plate). It was surprising that only four druselike formations were encountered, showing their rarity.

3. Epithelial Sphere

Many times, desquamated cells were noted; and once, the germinal zone detached and fell into the liquefied cortex. In a lens of the group of retinal detachments, cellular elements had agglutinated and formed a large sphere (fig. 26) that in life must have floated about in the fluid, just as an aggregation of endothelial cells may swim freely in the aqueous or attach itself to the iris and propagate.

4. Incipient Subcapsular Cataract (Anterior-Polar Cataract)

In a case of malignant melanoma of the choroid, the only changes noted were two small foci of cells under the anterior

capsule. They resembled giant cells with their many nuclei and homogeneous protoplasm (fig. 27). It was considered that they represented the initial stage in the formation of an anterior-polar cataract.

5. Absence of Epithelial Cells

In only two cases among the 185 examined was there a complete absence of epithelial cells. A "dead lens" in the strict sense of the word must be considered one of the rarest of intraocular pathologic findings.

SUMMARY

The lenses that showed the greatest proliferation belonged in the groups of corneal scars, spontaneous iritis, and detachment of the retina. These were the eyes in which a low-grade, chronic alteration in the metabolism had existed over the longest period.

The lenses that showed the least proliferation belonged in the groups of intraocular tumors and glaucoma. Death of the cells characterized the tumor cases, owing to the irritant poisons eliminated by the tumors as they became necrotic.

Fig. 28 (Samuels). A case of tuberculosis of the cornea. The anterior chamber is filled with granulation tissue containing giant cells. An extensive anterior-polar cataract has thrown the lens capsule into numerous deep folds.

That multiplication of cells was seldom seen in the glaucomatous globes was probably due to the fact that the cells were compressed between the swollen lens substance and the distended capsule. This may be the reason that, in glaucoma cases, an anterior-polar cataract is a clinical rarity.

GLAUCOMA CAPSULARE*

HARRY S. GRADLE, M.D., AND H. SAUL SUGAR, M.D.

Chicago

Some 20 years ago, Vogt coined the term "Glaucoma Capsulare" to describe a condition that he had observed in 17 cases. These presented a more or less typical form of simple glaucoma, to which was added the picture of exfoliation of the anterior capsule of the lens. He very shrewdly deduced that the debris of exfoliated material closed the outlets of the angle of the anterior chamber and thus produced the hypertension. This was purely theoretical on his part, for no gonioscopic examinations were made of these patients. He thought correctly, however, for the examination of the angle of the anterior chamber has suggested that his deductions are correct and but little has been added to the picture as he originally described it. Time, experience with a larger number of patients, and refinement of methods of examination have rounded out the picture so that today the disease known as Glaucoma Capsulare, may be regarded as an entity. The present total number of cases studied by us is 77, an addition of 26 to our previous series.

Before discussing the condition itself, it might be well to speak of its etiologic aspect, namely exfoliation of the anterior capsule of the lens. This in itself has been known for well over 100 years, although not in its relation to the disease under discussion, and has been the subject of much investigative work. The historic phase and the large bibliography were discussed in an article by Gradle and Sugar¹ and consequently need not be repeated here. The observations made previously

as to racial incidence have been amplified slightly. So far, we have seen only two instances of Glaucoma Capsulare in Negro Americans. The previous high incidence of Glaucoma Capsulare in patients of Greek birth (8 patients, 15.7 percent) of the original series, remained the same (12 patients, 15.6 percent) in the enlarged series. This is interesting in view of Trantas' finding of exfoliation in 18 percent of 237 Greek patients over 55 years of age.

ZONES OF CAPSULAR EXFOLIATION

Capsular exfoliation occurs in a relatively small number of patients, usually past the age of 55. It is manifested as an elevated scruffing on the anterior surface of the anterior lens capsule which represents a separation and opacification of the anterior layers of the anterior lens capsule. In all likelihood the condition is a result of senile degeneration, although the frequency of unilateral occurrence places some doubt on this idea (18 cases in this series).

The capsular exfoliation occurs in five distinct zones of the capsule. One, and sometimes two of the five, can be seen *only* gonioscopically. They may be listed as follows:

Zone I. There is a central annular disc on the anterior capsule of the lens, varying from 1 to 2.5 mm. in diameter. This is fairly translucent and usually homogeneous, although there may be a few white specks near the periphery. The edges are sharp and sometimes have a tendency toward curling. The size of the disc is apt to depend upon the size of the pupil, and it is sufficiently transparent so that there is no interference with vision.

*From the Illinois Eye and Ear Infirmary, Chicago. Under a grant from the W. K. Kellogg Foundation. Presented in part before the IVth Brazilian Congress of Ophthalmology, June, 1941.

Zone II. This is a fairly narrow, clear zone that surrounds the central disc. There is never any uniform opacity in this area, but mainly capsular shreds that are apt to be disengaged from their base. The semiopaque shreds are frequently arranged radially, corresponding possibly to the radial folds of the posterior surface of the iris. Owing to the movements of the iris under normal light stimuli, the exfoliations of this zone are usually partly or completely rubbed off, leaving the area clear. It is most probable that the majority of the shreds found floating in the aqueous have their origin from this area.

Zone III. This zone varies in size and, in the untreated eye, appears to begin about 3 mm. from the axis of the lens. It extends fairly well into the periphery, depending upon the extent to which the posterior surface of the iris is in contact with the anterior lens capsule. The entire area of the zone is apt to be involved, and the appearance of the exfoliations suggested the original term of "Kapselhautchen." In other words, it appears to be a fairly opaque membrane that resembles a very fine gray and white honeycomb. The central edge is frequently lifted and curled and from this edge come some of the capsular shreds that are found free in the aqueous, as is shown by the irregular and frayed character of the axial edge.

Zone IV. Extending well up to the anterior insertion of the zonule of Zinn fibers is this narrow translucent zone with only irregular radial opacifications from Zone III extending into its axial portion. This zone can be seen only through a coloboma of the iris or else gonioscopically in iridectomized eyes. It does not play any role in the production of glaucoma.

Zone V. This lies around the equator of the lens between the insertions of the

anterior and posterior zonule fibers. The exfoliation here is the same as in Zone III. However, it seems unlikely that the exfoliations here are much concerned in the production of Glaucoma Capsulare. Opacification of the zonule fibers, themselves, is always present, when visible gonioscopically.

When the exfoliations are still adherent to the capsule from which they originate, their appearance varies from thin, flocculent shreds to that of a semicystic membrane that resembles a very fine mesh honeycomb. Histologically, it has been proved by numerous investigators that the exfoliations represent the outermost laminae of the anterior capsule of the lens. These are elevated by the development of vacuoles within the anterior layers of the capsule as was shown by Sobhy Bey in 1932.² The vacuoles then rupture under the influence of the rubbing movements by the posterior surface of the iris and the broken edges retract and curl up. As the movements continue, the exfoliations become loosened and float away in the normal aqueous current. It was interesting to note that, in one unoperated patient who had been on miotics for six years during the war, further vacuole formation occurred in the clear area of Zone II and was not rubbed off due to immobilization of the iris.

Apart from their appearance on the lens capsule, shreds of exfoliations of the capsule are frequently seen adherent to the iris. They seem to be somewhat tenacious in character and frequently become adherent to whatever portion of intraocular tissue with which they come into contact. As a result, the majority of the shreds are found on or around the pupillary border of the iris in a fairly fixed position. Occasionally one can be seen lying on the anterior surface of the iris. In some instances, we have seen them

adherent to the posterior surface of the cornea, either in the central areas or in the chamber angle.

Thus is explained the origin of what may be termed "foreign matter" in the anterior chamber of the eye. As the natural flow of the aqueous is toward the angle of the anterior chamber, it is perfectly proper to recognize that such foreign particles, aided by gravity and convection currents, will eventually come to lodge in the angle. The presence of these exfoliated shreds on the trabecular wall has been shown gonioscopically. In addition, there is always present a dense pigment ring due to the deposition of rubbed-off pigment granules in the trabecular spaces. The presence of both probably causes mechanical blockage of the spaces.

It stands to reason that not every case of exfoliation of the anterior lens capsule will develop hypertension, as Vogt originally contended. As the exfoliated material and pigment gradually block the trabecular spaces, the normal amount of drainage of the aqueous is lessened. But that decrease is compensated for by drainage through the remaining open spaces and probably by absorption through the crypts of the anterior surface of the iris. Only when the total drainage area has been reduced to a point where the production of the aqueous is greater than the possible elimination, does the intraocular pressure begin to increase. The process is slow, however, and probably requires years before the balance of intraocular pressure is disturbed. Consequently, there is no sudden rise in tension such as is found in an acute blockage of the chamber angles, but rather a slow increase in pressure with consequent vascular compensation.

COINCIDENTAL ACUTE GLAUCOMA

In only two cases of capsular exfoliation have we seen acute glaucoma occur.

Both had shallow chambers and angles and should be considered as "primary" acute glaucomas and not as Glaucoma Capsulare. The exfoliation was probably coincidental in each instance.

The case histories of the patients with capsular exfoliation and coincidental acute glaucoma follow:

Case 1. C. C., aged 66 years, experienced a sudden attack of acute pain in his left eye and noticed rings around lights on May 18, 1940. This patient was seen at the Illinois Eye and Ear Infirmary four days later. The tonometric readings were 25 mm. Hg (Schiotz) for the right eye; and 73 mm. for the left. All the typical findings of a congestive attack of acute glaucoma were present in the left eye. Both anterior chambers were shallow. Capsular exfoliation was present in each eye. The left eye did not respond to miotic therapy but remained normal after an iridectomy.

Case 2. J. F., aged 71 years, suddenly noticed poor vision in his right eye in September, 1939. On examination the tonometric reading for the right eye was 60 mm. Hg (Schiotz). Both anterior chambers were shallow. Eserine rapidly brought the tension to 32 mm. Typical capsular exfoliation was present in the right eye only. The lens of the right eye was cataractous and was operated upon. In spite of an open angle, the right eye responded like most eyes with Glaucoma Capsulare with slightly increased tension.

In March, 1946, the patient was being prepared for removal of a cataract from the left eye, the one without capsular exfoliation. Preoperative dilatation of the pupil of the left eye caused an elevation of tension from 25 to 49 mm. Hg (Schiotz) in two hours and return to normal after eserine.

In two other cases, vascular decompensation occurred, probably as a break in the vascular compensation of a previously long-standing Glaucoma Capsu-

lare. In these cases, the chambers were deep and the angles open. In one case, that of J. L., aged 65 years, there were no symptoms except for decreased vision over a long period, until three weeks before examination in 1939. At this time, the left eye became painful. The vision was 9/200 in this eye and could not be improved. The lens was clear. The disc was deeply cupped. There was no evidence of any abnormal narrowing of the angle. In the second case, that of J. P., aged 65 years, in 1938, the visual acuity of the left eye began to decrease 13 years previously. Two years later the eye was amaurotic. There was no pain until February, 1936, when the tension of the left eye was 77 mm. Hg (Schiotz). The eye was red without evidence of an inflammatory or angle-block basis. A trephining operation was done on this eye.

In just what percentage of cases with capsular exfoliation glaucoma develops, it is impossible to say. In our series of 77 cases of exfoliation, glaucoma developed in 63 (81.8 percent). In the literature, the incidence varies from 14.0 percent (Alling³) to 90.0 percent (Busacca⁴). Inasmuch as the exfoliation usually can be detected only with slitlamp or loupe, and then often requires pupillary dilatation, it will be necessary to examine many thousand patients to determine the exact percentage that develop glaucoma. One of us (H. S. G.) has followed a patient with capsular exfoliation for 18 years and has never found hypertension, nor has her lens opacity progressed to a point necessitating extraction. On the other hand, we have observed the development of glaucoma in four patients with exfoliation after several months of observation. We may not say with any degree of certainty that the presence of capsular exfoliation always presumes the eventual development of glaucoma but, at least, glaucoma does occur in a large percentage of cases.

Conversely, we do not know what percentage of cases diagnosed as simple glaucoma are of the type which are really Glaucoma Capsulare. In our previous series of simple glaucoma in the glaucoma clinic of the Illinois Eye and Ear Infirmary, there were 331 cases up to July 31, 1940, as compared to 46 cases with Glaucoma Capsulare. It appears that about 7.2 percent of the cases heretofore diagnosed and treated as primary simple glaucoma are, in reality, secondary glaucoma of the type known as capsular and requiring, in many instances, a different form of therapy.

DIFFERENTIATION BETWEEN SIMPLE GLAUCOMA AND GLAUCOMA CAPSULARE

There are but few distinguishing characteristics between primary simple glaucoma and Glaucoma Capsulare as regards their course, and these have to be detected by slitlamp and gonioscopic study. Both conditions are insidious in nature, and patients having each type are often not seen until one eye has become totally blind. There is a tendency to spontaneous and operative dislocation of the lens and to the occurrence of asteroid hyalitis in eyes with capsular exfoliation, not in simple glaucoma. Asteroid hyalitis was present in 7 patients of the 77 examined by us. In two, there was spontaneous dislocation of one crystalline lens. In several, the dislocation occurred just after section during cataract operations. In those instances where the capsular exfoliation was unilateral, the vitreous opacities were present only in that eye and not in the normal eye.

The visual acuity and visual field changes that develop are comparable to those of simple glaucoma; they are due to the influence of pressure, purely and simply. However, in Glaucoma Capsulare there is apparently a tendency for the pressure changes to occur with lower intraocular pressure, even pressures ordinarily

considered to be within normal limits. An example of such a case follows:

W. K., aged 78 years in 1939, had noticed, in 1936, that vision in the right eye, previously normal, was entirely gone. When seen at the Infirmary in February, 1937, the right eye was amaurotic; vision in the left eye was 20/20. The tonometric readings were 44 mm. Hg (Schiotz) for the right eye; 29 mm. for the left. The visual field of the left eye for a 3 mm. white target was normal. Tension in the left eye thereafter remained between 16 mm. and 28 mm. (28 once), yet the visual fields gradually decreased, concentrically, to 50 degrees, temporally, and 40 degrees, nasally, with the same target. Visual acuity remained at 20/30 until last seen in March, 1943.

Provocative tests in cases of Glaucoma Capsulare give the same results as in simple glaucoma (except, of course, in mixed cases). Anterior-chamber puncture was positive, while dilatation tests were negative in the following case:

J. U., aged 75 years, began to notice failing vision in 1936. When examined at the Infirmary in April, 1939, the visual acuity was 3/200 right and 20/25 left, corrected. Tonometric readings were 24 mm. Hg (Schiotz) for the right eye; 48 mm. for the left. On miotics the tension remained controlled, usually. Provocative dilatations with euphthalmine and homatropine were negative. Anterior-chamber puncture of the right eye gave the following results: Tension before puncture 23 mm.; tension one-half hour after puncture 10 mm.; one hour after puncture 21.5 mm.; 1½ hours after puncture 60 mm.; two hours after puncture 60 mm.; 2½ hours after puncture 60 mm. The aqueous volume removed on puncture was 0.24 c.c.

In another case of Glaucoma Capsulare with shallow anterior chambers, the response to anterior-chamber puncture was

of the type usually obtained in eyes with simple glaucoma with very shallow chambers.⁵ This patient, E. McD., aged 75 years, was seen at the Infirmary in August, 1939. There was negative response to pupillary dilatation with euphthalmine and homatropine. Anterior-chamber puncture of the right eye gave the following results: Tension before puncture was 28 mm. Hg (Schiotz). Withdrawal of 0.15 c.c. of aqueous was followed by tonometric readings of 8 mm. in one-half hour; 28 mm. in one hour, 32.5 mm. in 1½ hours; 37.5 mm. in two hours; and 35 mm. in 2½ hours.

With the slitlamp, exfoliated shreds may be seen adherent to the posterior surface of the cornea, usually nearer the periphery than the center. Similar small shreds may be found floating in the convection currents in the anterior chamber. The appearance of capsular material adherent to the iris was mentioned previously, but care must be taken to differentiate these shreds from the small gray nodules or tags that are seen so frequently in chronic cyclitis. Free pigment granules are seen very frequently. They may be adherent to the posterior surface of the cornea, may be floating freely in the aqueous, or may lie on the surface of the iris. Such granules are very minute, are light brown in color, and do not seem to have any tenacious qualities.

With the gonioscope itself, the differentiation between Glaucoma Capsulare and simple glaucoma is usually possible. In both types, the angle is usually of normal depth, at least in unmixed cases. In Glaucoma Capsulare, the angle usually presents a more or less characteristic appearance of slight veiling due to the presence of exfoliated lens-capsule material and a characteristic dense, trabecular pigment ring produced by the deposition of pigment granules in the trabecular spaces.

Adhesions are not usually present in the chamber angle in unoperated cases of Glaucoma Capsulare, except in the few instances where congestion has supervened in long-standing cases. Even after operative procedures have been performed, there is comparatively little tendency for the formation of these adhesions, probably due to the insulating effect of the minute capsular particles on the angle wall.

In addition to the above findings in the anterior segment, changes occur in the lens and vitreous. The lens contained within the capsule may be perfectly clear, but usually shows beginning opacities, not infrequently of the posterior-subcapsular type. Among the characteristic findings of a true Glaucoma Capsulare, these lenticular opacities play no diagnostic roles. However, more or less degeneration of the vitreous is always present. This may be comparatively minor and represented only by slight degeneration of the normal fiber structure; or again, there may be extensive degenerative changes, including asteroid hyalitis, or marked fluidity. In a large share of the cases, there is sufficient opacity of the lens so that the vitreous cannot be studied accurately and only when the lens is removed will the degenerative phases of the vitreous become manifest.

Cupping of the optic nerve heads proceeds apace with the amount and duration of the hypertension. As is well known, an acute increase in pressure does not cause a pathologic excavation of the disc. This results only from long-continued pressure that is above the resistance point of the lamina. The visual acuity and visual-field disturbances that are found in Glaucoma Capsulare are a direct result of the pressure increase and resultant cupping of the nerve head.

The successful management of Glaucoma Capsulare requires rather keen

judgment on the part of the ophthalmologist. The majority of cases require surgical interference, and the patient must be carefully informed that vision can only be maintained at its present level, as far as the effects of the glaucoma itself are concerned, but not improved. A few cases can be controlled successfully by the use of a miotic of sufficient strength and frequency of instillation to hold the pupil contracted and rigid. The effect in those cases is the same as in simple glaucoma but, in addition, there is resultant failure to rub off any more exfoliated material, thus preventing further clogging of the trabecular spaces. Only in the early cases, however, and in those in which the hypertension has caused but little damage is that treatment adequate.

In many cases, some form of surgical procedure is indicated. If cataract is present, lens extraction should be performed if the tension can be reduced preoperatively. Otherwise, a cyclodialysis or filtering operation must be performed first. Since there is a tendency for the drainage path to be closed by further exfoliated shreds carried there from the lens surface by the newly diverted current of the aqueous, any glaucoma operation must be followed by the constant use of miotics to prevent further exfoliation from the capsule. In view of the tendency for progressive loss of vision and field even without much elevation of intraocular pressure, surgery should be resorted to if definite progressive field changes are found.

It is interesting that, in spite of the idea that lens extraction is advocated in the treatment of Glaucoma Capsulare, the actual lens removal has no great effect on the ocular hypertension. Of 16 eyes in which the lenses were removed, 14 had tonometric readings of over 30 mm. Hg (Schiotz), as indicated in Table 1, at least once postoperatively. Fortu-

TABLE 1
RESULTS OF LENS REMOVAL IN GLAUCOMA CAPSULAR CASES AT THE ILLINOIS
EYE AND EAR INFIRMARY

Name	Highest Tension Preoperatively mm. Hg (Schiötz)	Type of Operation	Description of Chamber Angle, Postoperatively	Highest Tension, Postoperatively	Method Used to Relieve Tension
1. C.G.	45	Extracapsular	—(1937)	52	Cyclodialysis plus miotics
2. J.F.	60	Extracapsular	Partly open	38	Miotics
3. G.D. (R)	32	Intracapsular (vitreous loss)	Partly open, obliterated only in wound area	37.5	Miotics
4. G.D. (L)	76	Intracapsular (vitreous loss)	Palpebral fissure too small	46	Cyclodialysis repeated
5. B.P. (R)	26	Intraocular	Partly open	32	Miotics
6. B.P. (L)	32.5	Loop	Open below, obliterated upper half	32.5	Miotics
7. F.U. (R)	45	Extracapsular	Partly open	33	Miotics
8. F.U. (L)	32	Extracapsular	Partly open	35	Miotics
9. J.P.	48	Extracapsular	Open below, closed upper half	53	Miotics
10. M.S.	19	Extracapsular	Partly open, partly trabecular adhesions	52	Miotics
11. T.F. (R)	35	Intracapsular	Not seen	30.5	Miotics
12. T.F. (L)	48	Extracapsular	Partly open	30.5	Miotics
13. A.T. (R)	40 (normal after trephining)	Extracapsular	Partly open	33	Miotics
14. C.C. (L)	73 (normal after trephining)	Extracapsular	Partly open	29	None
15. A.McK. (L)	24	Intracapsular	Not seen	10 (1 month followup)	None
16. E.McD. (R)	28.8	Extracapsular	Open except for trabecular adhesion	38	Miotics

nately 12 were controlled with miotics and only two required cyclodialysis. Of course, removal of the lens does remove the possibility of further exfoliation and further trabecular blockage, but lens removal in cases of capsular exfoliation is not without danger because of the great

tendency toward lens dislocation and the loss of fluid vitreous, especially with intracapsular operations.

Such is the picture of the clinical entity now recognized fully and known as Glaucoma Capsulare. Only time can tell how frequently the condition occurs. Certain

it is that Glaucoma Capsulare is not rare overlooking the diagnostic points.
and that we must be on guard to prevent 58 East Washington Street (2).

ESERINE: ITS HISTORY IN THE PRACTICE OF OPHTHALMOLOGY*

(PHYSOSTIGMINE: PHYSOSTIGMA VENENOSUM (BALFOUR): (CALABAR BEAN)

FRANK H. RODIN, M.D.

San Francisco

No drug employed in the practice of ophthalmology offers such a fascinating story to the medical historian as eserine. By the irony of fate this substance, which was used as an ordeal poison by primitive peoples, later proved to be one of the most effective agents in therapy of the eye. The natural product from which the drug was derived is *Physostigma venenosum* (Balfour) or Calabar bean. After extensive experimentation and observation, the active principle physostigmine was isolated by Fraser¹ in 1863, and made to serve a great variety of medical therapeutic needs. Foremost among these was oculotherapy, and at the present time eserine (physostigmine) maintains an unchallenged place as a miotic.

The need of a miotic was recognized by the early ophthalmologists and, as late as 1861, Stellwag von Carion² in his famous textbook lamented the fact that: "We possess no means of effecting contraction of the pupil." Synthesis of the

drug was accomplished in 1935 by Julian and Piki.³

Trial by ordeal is a practice of extremely ancient origin. It may be generally stated to have been exercised in every country and by every race from early barbarity and to persist to some degree even today. The ancient annals of Greece (*Antigone* of Sophocles, volume 270) tell of its existence. The Bible contains one of the earliest accounts of such a trial, at which a "cup of bitter water" was commanded to be drunk for the detection of conjugal unfaithfulness (*Book of Numbers*, chapter 5, verses 17-31). In Hindustan, China, Japan, Java, the Canary Islands, and many other lands, various forms of ordeal were, and perhaps still are, utilized. In Europe, notably in England, the practice remained in force until the 13th century, when, during the reign of Henry III, a law was reportedly passed for its abolishment (*Blackstone's Commentaries*, volume 4).

Ordeals may be classified under two great headings: those in which application is external, and those in which it is in-

* From the Division of Ophthalmology, Stanford University School of Medicine.

ternal. The first class includes the well-known trials by fire, water, combat, and the balance. The second, comprising perhaps the most curious and interesting forms, encompasses a large section of the vegetable ordeal poisons. Some of these are beans, nuts, barks, roots, and trees, and it is to this group that the Calabar bean belongs.

Calabar bean is the seed of a leguminous plant, *Physostigma venenosum* (Balfour), indigenous to tropical Africa. The climbing plant grows to a height of about 50 feet on a stem one to two inches thick. The seed pods are six to seven inches long, each containing two or three chocolate-colored seeds or beans about the size of a broad bean. Nothing in the appearance, taste, or smell of the Calabar bean distinguishes it from the harmless varieties which it resembles.

PHYSIOLOGIC EFFECTS

Eserine does not affect unbroken skin. Ingestion of it at first greatly increases salivation by its direct action on secretory cells; then arrests it, due to the constricting effect of the drug on the blood vessels supplying the salivary glands. The secretion of bile, tears, and sweat is likewise affected. A rise in blood pressure occurs. The pharynx becomes constricted, and vomiting and purging ensue. The spleen, uterus, bladder, and iris are also involved. Early, the heart beat is reduced in rate secondary to stimulation of the terminals of the vagus nerve; later, depression of the intracardiac motor ganglia prolongs diastole and eventually halts the action of the heart in dilatation. The initial influence of eserine on respiration is that of acceleration, owing to stimulation of the pulmonary ending of the vagus. This condition is supplanted by retardation and ultimate arrest of breathing when paralysis of the respiratory center in the medulla oblongata takes place, en-

hanced by contraction of unstriped muscular tissue in the bronchial tubes and accumulation of increased bronchial secretion. Action on muscular tissue is direct, since it can occur in the presence of motor-nerve paralysis, and very large doses are required to produce voluntary-muscle intoxication or tremor.

The medulla is apparently the highest level of the brain affected by eserine, and consciousness is not altered. However, spinal-cord reflexes are abolished due to the direct influence of the drug on the cells of the anterior cornua. Reduced sensitivity shortly before death corresponds to sensory-cord paralysis.

Daniell,⁴ a British Army medical officer stationed at Calabar, was first to observe the use of the Calabar bean. William Freeman Daniell was born in Liverpool, in 1818. In 1841, he became a member of the Royal College of Surgeons of England, and entered the medical service of the British Army. He served on the pestilential coast of West Africa and returned to England in 1863. Later, he accompanied the "Expeditionary Force" to China, and was present at the taking of Peking. A short time afterward he travelled to West India; on his next homecoming his health was broken, and he died in 1865.

While in foreign service, Daniell collected and described many native plants. His publications are concerned with the plants, trees, shrubs, and their fruits which were indigenous to the countries visited by him. One of his treatises deals with the Katemfé or miraculous fruit of the Sudan, which was afterward named *Phrynum Danielli*, Benn., in compliment to the botanist who first studied it.

Daniell first observed the use of the Calabar bean in native judicial procedure about 1840. A communication read by him before the Ethnological Society of Edinburgh, in 1846, contains the first

known record of its application.

Old Calabar (fig. 1) is a district of West Africa in the neighborhood of the Bight of Biafra, which extends along the course of a large river, the Rio Calbary, Old Calabar, or Oude Calburgh. It is situated between 4 and 8 degrees North latitude, and 6 and 12 degrees East longi-

were middle men between the white traders on the coast and the tribes of the Cross River and Calabar district. Until 1904, Calabar was generally and officially known as Old Calabar to distinguish it from new Calabar; the name of a river and port, some distance to the east.

Old Calabar was a despotic monarchy,

Fig. 1 (Rodin). Map showing location of Calabar (center of the circle). It is located on the river Calabar, a district of West Africa in the neighborhood of the Bight of Biafra.

tude; its estimated length is 100 miles and its breadth, 50.

Calabar was the name given by the Portuguese discoverers of the 15th century to the tribes of this part of the Guinea coast. It was not until the early part of the 18th century that the Efik, after the civil war waged against the Ibibio, migrated from the neighborhood of the Niger to the shores of the River Calabar. The native inhabitants are still mainly Efik. For several generations, they

whose court of justice was composed of its king and elders. Prisoners judged by this body and decided guilty of certain offenses were obliged to swallow a deadly poison. This poison was obtained by grinding and macerating in water the seeds of the Calabar bean, called Esére by the natives, until the solution was milky white. After the prisoner had swallowed the poison, he was made to walk continuously until the poison took effect. If, however, after the lapse of a prede-

terminated period the accused vomited the poison, his innocence was considered vindicated, and he was freed of his charge.

Robert Christison⁵ (fig. 2), in 1855, was first to experiment with the Calabar bean. He was born in Edinburgh, in 1797, the son of a professor of humanity

Fig. 2 (Rodin). Robert Christison who was the first to experiment with the Calabar bean.

(Latin) at the University of Edinburgh. He became interested in toxicology, and between 1822 and 1832 held the chair of medical jurisprudence at the University. His reputation as a medical jurist was well established by his famous book, *A Treatise of Poisons*, published in 1829. In 1832, he was transferred to the chair of materia medica, which he held for 45 years. His studies in this field earned him a reputation at least equal to that which he had won in medical jurisprudence. In 1842, he published his famous "dispensatory," giving in great detail the obvious effects that followed the administration of remedies in disease and laboratory classification of them. As chairman of the Committee of the General Medical Council, he helped to harmonize the pharmacopoeias of England, Scotland, and Ireland into a National Codex.

Christison was twice president of the

Royal College of Physicians in Edinburgh and was also elected president of the Royal Society of Edinburgh. A baronetcy was conferred upon him in 1871. He became a famous practitioner, with one of the largest and most lucrative practices in Scotland. He died in 1882. Among the many honorary appointments bestowed upon him were membership of the Pharmaceutical College of New York, member of the American Philosophical Society, and associate of the American College of Surgeons of Philadelphia.

Christison's interest in the Calabar bean was aroused when a missionary sent him one which two of his colleagues cultivated for him. He not only tried the seed on animals, but ate some of it himself. His description of his experience is so animated and charming, and portrays so vividly the character of the experimenter, that I shall let him speak for himself.

Having ascertained the mode of death from the action of the ordeal-bean, I did not consider it advisable to study further the details of its action by means of experiments on animals, because I had been fully informed as to this in a more precise manner by an experiment made with the bean in my own person. I shall conclude this notice with an account of what I experienced; and I trust the details will not appear needlessly minute, as they seem to me to establish an action of a very singular kind in the case of this poison, and one of which we might discover other instances among known poisons, had we equally precise opportunities of determining the true phenomena.

Having some doubts whether I had obtained the true ordeal-poison, as it tasted so like an eatable leguminous seed, I ate one evening the eighth part of a seed, or six grains, about an hour after a very scanty supper. During an hour that I passed in bed reading, I could still observe no effect whatever, and next morning I could still observe none. I am now satisfied, however, that a certain pleasant feeling of slight numbness in the limbs, like that which precedes the sleep caused by opium or morphia, and which I remarked when awake for a minute twice or thrice during the night, must have been owing to the poison.

On getting up in the morning I carefully chewed and swallowed twice as much, viz., the fourth of a seed, which originally weighed

forty-eight grains. A slight giddiness, which occurred in fifteen minutes, was ascribed to the force of the imagination; and I proceeded to take a warm shower bath; which process, with the subsequent scrubbing, might take up five or six minutes more. The giddiness was then very decided, and was attended with the peculiar, indescribable torpidity over the whole frame which attends the action of opium and Indian hemp in medicinal doses. Being now quite satisfied that I had got hold of a very energetic poison, I took immediate means for getting quit of it, by swallowing the shaving water I had just been using, by which the stomach was effectually emptied. Nevertheless I presently became so giddy, weak, and faint, that I was glad to lie down supine in bed. The faintness continuing great, but without any uneasy feeling, I rung for my son, told him distinctly my state, the cause, and my remedy—that I had no feeling of alarm, but that for his satisfaction he had better send for a medical friend. Dr. Simpson, who was the nearest, reached me in a few minutes, within forty minutes after I ate the seed, and found me very prostrate and pale, the heart and pulse extremely feeble and tumultuously irregular; my condition altogether very like that induced by profuse flooding after delivery; but my mental faculties quite entire, and my only sensation that of extreme faintness, not, however, unpleasant. Dr. Simpson judged it right to proceed at once for Dr. Douglas MacLagen as a toxicological authority, and returned with him in a very few minutes.

In his absence, feeling sick, I tried to raise myself on my elbow to vomit, but failed. I made a second more vigorous effort, but scarcely moved. At once it struck me—"this is not debility, but volition is inoperative." In a third effort I was more nearly successful; and in the fourth, a resolute exercise of the will, I did succeed. But I could not vomit. The abdominal muscles acted too feebly; nor were they much aided by a voluntary effort to make them act. I then gave up the attempt, and fell back, comforting myself with the reflection that vomiting was unnecessary, as the stomach had been thoroughly cleared. At the same time the sickness ceased, and it never returned. There were now slight twitches across the pectoral muscles. I also felt a sluggishness of articulation, and, to avoid any show of this, made a strong effort of the will to speak slowly and firmly, through fear of alarming my son, who was alone with me.

Dr. MacLagen, on his arrival, thought my state very like the effects of an overdose of aconite. Like Dr. Simpson, he found the pulse and action of the heart very feeble, frequent, and most irregular, the countenance very pale, the prostration great, the mental faculties unimpaired, unless perhaps it might be that I felt no alarm where my friends saw some reason for it. I had,

in fact, no uneasy feeling of any kind, no pain, no numbness, no prickling, not even any sense of suffering from the great faintness of the heart's action; and as for alarm, though conscious I had got more than I had counted on, I could also calculate, that, if six grains had no effect, twelve could not be deadly, when the stomach had been so well cleared out.

Presently my limbs became chill, with a vague feeling of discomfort. But warmth to the feet relieved this, and a sinapism over the whole abdomen was peculiarly grateful when it began to act. Soon afterwards the pulse improved in volume, but not in regularity. I was now able to turn in bed; and happening to get upon the left side, my attention was, for the first time, directed to the extremely tumultuous action of the heart, which compelled me to turn again on the back, to escape the strange sensation. Two hours after the poison was swallowed, I became drowsy, and slept for two hours more; but the mind was so active all the while, that I was not conscious of having been asleep. On awaking, the tumultuous action of the heart continued. In an hour more, however, I took a cup of strong coffee; after which I speedily felt an undefinable change within me, and on examining the condition of the heart, I found it had become perfectly and permanently regular.

For the rest of the forenoon I felt too weak to care to leave my bed; and on getting up, after a tolerable dinner, I was so giddy as to be glad to betake myself to the sofa for the evening. Next morning, after a sound sleep, I was quite well.

It is interesting that, while Christison was under the effect of the drug, he did not notice its action on the eye.

Typical of the old professors of Edinburgh, who were not only scientists and teachers but philosophers as well, Christison made the following observations concerning the possible use of the Calabar bean for the execution of criminals.

Let me advert lastly to a peculiarity in the action of the ordeal-bean which struck me forcibly while labouring under it. Philosophers have thought it not unworthy of inquiry, how in criminal executions death may be completed without physical suffering to the criminal. Governments have even consulted science on the subject. But science has not yet satisfactorily solved the question. Meanwhile, I suspect it has been accidentally solved by the negroes of Old Calabar. At least, so far as the effects of their state-poison on myself went, there was no bodily uneasiness except the single attack of sickness—apparently the relics of the action of my pe-

cular emetic—but simply a sense of sinking vitality, with clearness of mind, and without any sensation deserving in the slightest degree to be called physical distress. We know, indeed, that many forms of extreme fainting, of which this is evidently one, are attended with feelings, which if not positively pleasurable, are certainly quite unallied to pain. Death by simple fainting, without any preparatory painful process, is evidently what a humane execution should aim at producing. And all this, I apprehend, will be effected by the Calabar Ordeal-bean.

Thomas R. Fraser¹ (fig. 3), who had been Christison's assistant, continued this

Fig. 3 (Rodin). Thomas R. Fraser, the first to isolate the active principle, physostigmine.

study, and in his graduation thesis, in 1862, discussed the action of the Calabar bean.

In 1863, he separated from the kernel (the spermoderm of the bean) and later from the excrement of a lepidopterous insect which feeds on the kernel, an amorphous active principle with the properties of a vegetable alkaloid. He proposed the name Eserina for this alkaloid derived from Esère, as the ordeal poison is called in Calabar. Some time later, he obtained a

purier, crystalline form of the alkaloid, which he called Eseria.

Fraser was one of the Big Five (Sir Douglas Maclagan, Sir Thomas Grainer Stewart, Sir Alexander Simpson, Professor Greenfield) who gave greatness to medicine at the University of Edinburgh in the second half of the 19th century. All of them practiced clinical medicine and, at the same time, held chairs in a single specialty at the University. Under their leadership, the university teaching of medicine progressed to brilliant heights.

Fraser, born at Calcutta in 1841, died at 79 years of age. He was educated at the public schools in Scotland and at the University of Edinburgh, where he received a gold medal for his thesis on the Calabar bean. When Christison resigned, Fraser was appointed to his chair in pharmacology. Many honors were bestowed upon him. In 1903, he was knighted by King Edward VII.

After the publication of his work on Calabar bean, his research led to the study of other ordeal and arrow poisons. His best known contribution deals with *Strophanthus* and *Acocanthera*. Following his investigation of Calabar bean, he became interested in the subject of antagonism in general, and in that of physostigmine and atropine in particular. He regarded pharmacology as one of the means by which the healing of disease could be reached. He substituted for old methods in which the effects of drugs were studied through their administration in disease, a newer science in which, after the essential nature of the pathologic process had been defined, accurate biologic and chemical knowledge was employed to produce the substance that should influence the perverted process. This application of pharmacologic knowledge to the cure of disease, a problem entirely separate from determining the action of remedies, was illustrated by his

earliest work in connection with physostigmine, its relation to atropine, and the uses of these two drugs in ophthalmic practice.

Fraser was first to observe contraction of the pupil associated with the use of physostigmine (fig. 4). He reported that the pupil contracts within a few minutes after physostigmine is applied to the eyeball, to the cutaneous surface in its neighborhood, or to the nasal mucous membrane. He found that application of Calabar-bean extract to the eyeball produces a somewhat painful sensation of tension in the ciliary region, contraction of the pupil, myopia, and astigmatism.

Fraser described the action of physostigmine on his own eye. He placed a small drop of the syrupy solution on the conjunctiva of the left eyeball. There was instantaneous copious discharge of tears. In five minutes, the pupil of the left eye was contracted to half the size of the right. In 10 minutes, the pupil was one-sixteenth-inch in diameter. Vision became imperfect, but the eye was mobile. There was a slightly painful sensation in the supraorbital region and a feeling of heat in the left eyeball. In 30 minutes, no change was observed in the pupil of the right eye, whereas that of the left eye was pinpoint in size.

Fraser noticed that vision of the left eye was greatly reduced. The eye was somewhat red and tender when exposed to light. In $1\frac{1}{2}$ hours, all disagreeable sensations had disappeared, dimness of vision was less marked, but the pupil remained contracted. In four hours, vision had returned to normal, but the pupil re-

mained contracted for 24 hours. After this it slowly dilated, and five days later had returned to normal.

Douglas Argyll Robertson (fig. 5), a practicing ophthalmologist, also experimented with the use of the drug and observed its action on the pupil. He was born in 1837, the son of a surgeon and

lecturer in the Edinburgh Medical School. He studied in Berlin under von Graefe. Upon returning to Edinburgh, he soon gained recognition as an ophthalmic sur-

geon, and was one of the founders of the Eye Dispensary. His present fame rests on his description, in 1869, of the Argyll Robertson pupil.

While practicing, Argyll Robertson conducted the first class in practical physiology at the University of Edinburgh. He was interested and well informed in all departments of medicine, and his choice of subject before the Ophthalmological Society of the United Kingdom in 1893, "Therapeutic Contributions of Ophthalmology to General Medicine," was characteristic of the man. He was appointed first assistant, then ophthalmic surgeon at the Infirmary. He was the first surgeon not residing in London to be elected president of the Ophthalmological Society of the United Kingdom.

A singularly attractive and gifted indi-

vidual, he was one who would have come to the front in any walk of life. He had distinguished bearing, courage, and sincerity. As a surgeon, he was neat, rapid, and resourceful. He was also an excellent teacher.

Argyll Robertson had been interested in the discovery of a substance which, when applied to the conjunctiva, would produce an effect exactly opposite to that of belladonna; one which would stimulate the muscle of accommodation and the sphincter pupillae as atropine paralyzes them. He tried various drugs without satisfactory results. When Fraser in-

formed him that he had seen contraction of the pupil result from local application of Calabar-bean extract, Argyll Robertson used it on his own eyes⁶ (fig. 6).

He noticed that the substance contracts the pupil and affects accommodation, causing indistinct vision of distant objects. He also observed that accommodation is first to return, before the pupil resumes normal size. Further, he instilled Calabar-bean extract followed by a drop of atropine. His experiments led him to believe that physostigmine and belladonna were antagonistic in their action on the eye.

Argyll Robertson did not realize the value of Calabar-bean extract as a miotic in glaucoma, but did suggest that it be applied after atropine preparatory to examination of the eyes. He also proposed its use for the relief of photophobia and paralysis of the ciliary muscle. Moreover, he believed it to be beneficial in cases of ulceration of the margin of the cornea leading to perforation, and even when prolapse of the iris had occurred.

Publication of the works of Fraser and Argyll Robertson incited great interest in the use of Calabar-bean extract for affections of the eye. One of the papers read at the first meeting of the American Ophthalmological Society, in 1864, by Dix of Boston, concerned the effect of Calabar-bean extract upon paralysis of accommodation following diphtheria.

Ludwig Laqueur⁷ (fig. 7) was the first ophthalmologist (March, 1875) to use physostigmine therapeutically in glaucoma. He noticed that it lowered intraocular pressure temporarily or permanently.

There was strong opposition to eserine when it was first used to treat glaucoma. Laqueur maintained his stand courageously in the face of resistance. He was fortunate to have as a supporter the veteran Snellen.⁸

Laqueur mentioned that Calabar-bean extract occasionally raises intraocular pressure, but not as much as atropine. Adamük also observed a slight rise in intraocular pressure after local application of Calabar-bean extract. This finally was contradicted by Adamük, von Hippel, and Grünhagen.⁹

Fig. 7 (Rodin). Ludwig Laqueur, who introduced the use of eserine in glaucoma.

Laqueur used the extract in treating more than 10 cases of advanced glaucoma simplex. The effect was not identical in every case; but reduction in tension was constant. After three or four days, often at the end of 24 hours, the effect disappeared. In other cases, reduced tension was more lasting, and a cumulative effect of reduced tension to subnormal for a considerable period was obtained. He noted that improvement in vision in glaucoma simplex did not occur, but that in many cases there was increase in the visual fields. To his credit, he felt that the series of cases was too small for him to make conclusions concerning the value of the drug in glaucoma simplex. He also used physostigmine successfully in three cases of subsiding glaucoma. These were mildly subacute cases, and reacted

promptly and definitely to physostigmine over a protracted period. He reported three cases of acute glaucoma and one of possible secondary glaucoma which were benefited by the use of physostigmine.

Laqueur makes the statement that physostigmine has a favorable effect, but that it does not supplant iridectomy; it acts only as an adjunct to surgery by making the technique easier.

Von Graefe¹⁰ also experimented with the Calabar bean, which he used to facilitate iridectomy, because the miotic effect facilitated the technique of operation.

From that time on, eserine has been used more and more extensively, and now it occupies a prominent place in the treatment of glaucoma.

EVALUATION OF THE NEWER THERAPEUTIC AGENTS IN OPHTHALMOLOGY*

ELMER A. VORISEK, M.D.

Chicago

Modern civilization calls for new and better products, and medicine, to keep step, must find newer methods of therapy which produce complete cures in a shorter period of time. Chemotherapy, because of the rapidity of its therapeutic effect, certainly called attention to the fact that modern medical therapeutics is almost as spectacular as radar and the atomic bomb. Pages are being written on the experimental and clinical application and results of sulfonamide and penicillin therapy.

As a result of present day enthusiasm for things new and modern, there is a tendency to overlook the all-potent therapeutic ability of Nature to heal the ailments of the living world, and it follows that this same Nature has tremendous ophthalmo-therapeutic powers. Walter Stanley Haines, who has probably been forgotten except for his Haines solution, applied a great deal of philosophy and good common sense to his teachings, and his definition of a "good doctor," given to the young medical student, contained the admonition that a "good doctor" never did anything which would hinder Nature in her attempt to effect a cure, and he cautioned the doctor "always to consider treatment as an aid to Nature's curative powers."

For a time, it seemed that the sulfonamides and penicillin would produce a revolution in modern therapeutics, but after time and experience had mellowed the initial enthusiasm, it became quite

evident that, although we were indeed more than fortunate to have these substances available to us, there were diseases which did not respond to their administration. It became necessary to evaluate these drugs properly, and to recognize, very early, those cases which would be most benefited by the use of chemotherapy. Sulfonamides and penicillin must not be used indiscriminately, particularly for minor infections. In ophthalmology, the usually accepted local therapy must still be faithfully carried out in the majority of instances.

If possible, a bacteriologic study should be made to determine whether or not the infection present is due to an organism which is susceptible to the action of these drugs. Every one realizes it is difficult to obtain a culture in the case of many external ocular infections, and, in these instances, chemotherapy will probably be instituted in spite of negative bacterial cultures.

SULFONAMIDE THERAPY

Contradictory reports on the value of the sulfonamides have been made by men of equal repute, and it is sometimes difficult to evaluate the pros and cons in the literature. Isolated case reports show miraculous cures, but some report failures. Through this dissemination of knowledge and experience, we are constantly learning more and more about the uses of the sulfonamides, and the final chapter remains to be written. Newer drugs of this group are still being discovered, and the clinical ophthalmologists, who greatly outnumber those in the research group, must be able to evaluate the information supplied in the literature, and

* Read May 20, 1946, before a special session of the Minnesota Academy of Ophthalmology and Otolaryngology at the 93d annual session of the Minnesota State Medical Association at St. Paul, Minnesota.

apply the same to everyday usefulness.

Penicillin is now frequently replacing the sulfonamides and has proved far superior in some instances. However, the ophthalmologist will still find much value in the use of sulfa both locally and orally. It appears that the sulfa ointments will replace yellow oxide in popularity. There is a tendency to use chemotherapy routinely for any infection, and, because of this tendency, some hospital records are of no value for statistical purposes. Single-dose chemotherapy, as ordinarily used, is valueless, except to impress the patient or his relatives with the fact that he has been given the latest drug which the public press is popularizing.

It must be remembered that the sulfonamides are merely bacteriostatic, and, when administered either orally or locally, they must be given in high enough doses and over a sufficient period of time to obtain not only an improvement, but a permanent cure.

Before sulfonamides are given orally, it is important that the urine and blood counts are normal and, during administration of the drug, the blood level must be maintained between 5 to 10 mg. per 100 c.c. Repeated urinalyses and blood counts must be made; alkalinity of blood and urine¹ must be maintained; high intakes of liquids are necessary; and accurate temperature recordings are required. Sunlight should be avoided to prevent possible cutaneous reactions on the basis of a photosensitization.

It behooves us to know that there are severe toxic manifestations in sensitive individuals, not only generalized but ocular as well, and toxic reactions occur after either oral administration or local application. Consequently, it is important to repeat that the sulfonamides should not be used indiscriminately for minor infections which do not warrant the risk of toxic reactions, although the

recent products are less toxic than the original ones. It has been our experience that systemic and local reactions are much more frequent than one would deduce from a perusal of the ophthalmic literature.

The possible toxic reactions which may be encountered are anemia, neutropenia, cyanosis, low white count, hyperpyrexia, severe gastroenteritis, neuritis, psychosis, renal calculi, kidney damage with anuria and hematuria, and dermatoses. A sore throat may indicate a beginning agranulocytosis. Ocular manifestations of oral medication have been variously reported as optic neuritis, retinal hemorrhages, "dimness of vision," "temporary blindness," field changes, conjunctival and scleral injection, yellow discoloration of sclera, a bluish tinge indicating cyanosis or anemia of the conjunctiva, and transient myopia.

Local application of sulfonamide ointment and solution has frequently produced marked irritation of the cornea and conjunctiva with redness and swelling of the lids. It causes delay in the healing and increases the vascularization and scar formation of the denuded or injured cornea. We must also realize that, although toxic phenomena may not immediately occur, an appreciable number of patients become sensitized to the drug and display toxic effects during subsequent administration. In any case, stopping the administration of the drug usually results in rapid recovery.

If the ophthalmologist realizes all these exceedingly important factors and carefully evaluates his cases, he is prepared to proceed with sulfonamide therapy toward the goal of obtaining maximum benefits and excellent results in the majority of cases for which these drugs are so aptly suited; but, he must bear in mind that atropine, heat, surgery, and all the other specific therapeutic procedures indicated,

must be carried out in conjunction with sulfonamide therapy.

Orally, the most effective sulfonamide is sulfadiazine in average doses of 1 gm. every four hours after an initial dose of 2 to 4 gm.; and locally, sulfathiazole as a 5- to 10-percent ointment or 1- to 10-percent sodium-salt solution, and either method alone, or together, may be indicated. Several foreign authors² recommend a 15-percent sodium-sulfacetamide collyrium.

The ophthalmic conditions which are favorably affected are: trachoma, inclusion-body blennorrhea, catarrhal conjunctivitis, staphylococcus, gonococcus, influenza-bacillus, colon-bacillus, and actinomyces infections, erysipelas, serpent ulcers, cellulitis of lids and orbit, dacryocystitis, endophthalmitis, panophthalmitis, and occasionally sympathetic ophthalmia.

As previously stated, penicillin is supplanting the sulfonamides in some types of infection, and especially is this true in gonorrheal ophthalmia, blepharitis, catarrhal conjunctivitis, and dacryocystitis. Nevertheless, penicillin may not be readily available; or full-strength, fresh solutions may not be practicable.

In blepharitis we have had the best results by rubbing the sulfathiazole ointment into the roots of the lashes. It usually acts most rapidly but, unless continued for sufficient periods of time, recurrences result. If recurrences do occur, staphylococcus toxoid used in conjunction with the sulfa ointment produces excellent results. If trichiasis should be present, the lashes must be epilated; and if the meibomian glands are involved, they must be mechanically expressed. Nor will sulfathiazole used locally cure a chalazion or hordeolum. In the presence of secretions or debris, the bacteriostatic action is inhibited.

The preponderance of evidence indicates that the sulfonamides are curative or

of great value in the treatment of trachoma, but there are a few leading authorities who believe that these drugs are ineffective.³ However, the sulfonamides, orally and locally, must be included in the treatment of trachoma,⁴⁻⁵ and other types of therapy will still be indicated in those cases in which sulfa therapy either fails to act or where a sensitivity to the drug exists.

In the case of inclusion-body blennorrhea, irrigation with a sodium-sulfathiazole solution every two hours, sulfa ointment at night, and sulfadiazine by mouth, produce excellent and very rapid improvement within seven to ten days as compared to six weeks with the previous types of therapy.

Similarly, the prolonged severe inflammation, with poor response to previous types of therapy which was encountered in the cases of membranous conjunctivitis, has been eliminated by the local use of the sulfonamides.

Catarrhal conjunctivitis responds very rapidly to the local use of the sulfa—both ointment and solution—but, in the presence of purulent discharges or anesthetics, the action is inhibited.

Excellent results are obtained in ulceration of the cornea, but here, as well as in traumatic destruction of the epithelium, results are obtained only when superimposed infection exists. The sulfonamides delay the healing of corneal ulcers⁶ and produce an increase in the amount of scar formation in a denuded or injured cornea and should not be used except in the presence of a superimposed infection.

It was most interesting to analyze the statistics of Smith⁷ of the Royal Hospital, Sheffield, in reference to hypopyon ulcers, for the years 1936 through 1944. The admission of patients with spontaneous ulcers averaged 24 per year, and those with traumatic ulcers 53 per year—39 with hypopyon and 14 less severe. Py-

rexial and local treatment remained essentially the same during this nine-year period, but in July, 1939, the treatment was combined with the internal administration of sulfanilamide, changing to other sulfonamides as these became popular. The average number of days hospitalization for the period 1936 through 1939 was: hypopyon ulcer, 19.6 days, and less severe ulcers, 13.0 days. Then there occurred a definite decrease in necessary hospitalization with the average in 1944 being: hypopyon ulcer, 12.5 days, and less severe ulcers, 7.5 days.

Since a high concentration of these drugs appears essential to an effective therapeutic result, the local use seems to be preferred over the systemic use. In cases of inclusion blennorrhoea, trachoma, and serpent ulcer, however, it has been proved that both oral and local administrations are required. There does occur some penetration of these drugs into the anterior chamber, but to induce this penetration it is necessary to utilize heat, paracentesis, wetting agents, and so forth.

In cases of cellulitis of the lids and orbit, endophthalmitis, and panophthalmitis, excellent results have been obtained through oral administration of large doses. However, the administration must be started very early, and continued for several days after complete recovery has occurred; and then, gradual reduction, rather than abrupt cessation of the drug, is to be preferred. If abscess formation occurs, it is absolutely necessary to incise and drain; otherwise, the suppurative material will not be absorbed.

Since the sulfonamides have been used so extensively for the treatment of meningococcal meningitis and scarlet fever, there has resulted a marked decrease in the number and severity of the complications. We are now aware of one to two cases per year of endophthalmitis as compared with eight to ten such complica-

tions only a few years ago. The same decrease in incidence applies to orbital abscesses and acute suppurative dacryocystitis. Sulfonamides not only cure the systemic infection swiftly but, in so doing, also prevent the serious complications. It is recalled that in several cases of complications, sulfa was not administered immediately but was withheld, pending diagnosis. This situation brings up the point that possibly, in these cases, the complications had already begun before the sulfonamide blood level was of sufficient concentration to control the bacterial activity. A reduction in the number of complications has also been noted in other instances besides ophthalmic; for example, the decrease in the incidence of mastoiditis, following middle-ear infections. We are prompted to repeat again, that in order to obtain satisfactory results, sulfonamide therapy must be begun early, given in high enough doses, and for a sufficient length of time.

Gamble⁸ reported the successful control of a case of sympathetic ophthalmia with sulfa, and since then he has had similar experiences with several other cases. I have had the privilege of following two of these cases. The most recent one, which is of about five months' duration and which is still under observation, develops periodic episodes of mild ciliary injection, without cells in the anterior chamber. In this case, an extensive dermatosis with hyperpyrexia developed, with immediate recovery when the drug was discontinued. This case will be referred to later.

Several other cases have been reported⁹ with control of the sympathetic ophthalmia, but some cases have also been reported as failures. Nevertheless, in this most dreadful of ophthalmic afflictions, sulfathiazole should be administered as soon as possible and in large doses.

There is a consensus of opinion that

sulfa is very beneficial as a prophylactic after intraocular injuries or after operations with threatened infection. Our experience would confirm this opinion, and no postoperative infections have occurred during the routine use of 5-percent sulfathiazole ointment, locally, or oral administration of sulfathiazole when indicated.

We have found the sulfonamides of little, if any, value in uveitis. An occasional report has been made purporting to have produced good results, but a perusal of the case reports leads us to be skeptical of the published conclusions. Many cases of uveitis regress under conservative treatment; whereas, others terminate unfortunately in spite of everything one may do. One has only to consider the vast number of quiescent lesions which are seen on routine ophthalmoscopic examination to appreciate that many cases of both anterior and posterior uveitis recover without any treatment, and without apparent knowledge of their existence by the patient. This is especially true of choroiditis.

In 1942, Levy and Lewis¹⁰ reported the successful use of the sulfonamides in 137 cases of gonorrheal conjunctivitis, and advocated both systemic and local applications, because results with local therapy alone did not compare favorably with the internal use of the drug. Successful reports^{11,12,20} have also been published in relation to ophthalmia neonatorum, but in both of these instances we believe that the sulfonamides will be completely eclipsed by the miraculous results of penicillin therapy. There seems to be no justification in subjecting a two-weeks-old baby to oral sulfonamide.

PENICILLIN

Whereas the sulfonamides are merely bacteriostatic, penicillin actually kills organisms, and it is probably because of this ability that the latter is gradually re-

placing the former in ocular therapeutics.

Penicillin may be administered systemically or locally or both, and is also used locally in conjunction with the oral administration of the sulfonamides. Like the sulfonamides, penicillin can be administered intramuscularly or intravenously, but it cannot be given orally in simple solution because the acid gastric juice destroys its action. When applied locally, any acid substance like boric acid or the adrenalin hydrochloride¹³ will inhibit the action of penicillin. It cannot be regarded as a nontoxic substance or a readily diffusible one.

Last April a report¹⁴ was published describing the oral use of penicillin in conjunction with aluminum dihydroxy-amino acetate. Eleven cases of external disease and four cases of uveitis were reported. Rapid cures were obtained in the majority of cases, but three cases of external infections and the four cases of uveitis failed to respond.

Generally speaking, Gram-positive organisms are sensitive, and Gram-negative ones are insensitive; staphylococcus aureus, streptococcus pyogenes, the gonococcus, and the meningococcus are sensitive; the pneumococcus is only moderately or slightly sensitive, according to type; the hemophilic group is relatively insensitive, but all insensitive organisms seem to respond to very strong concentrations of penicillin; and the sensitivity varies widely with different strains of the same organism. Acquired resistance frequently occurs. The only incompatibility is the acid radical; and, very fortunately, the common ophthalmic drugs—atropine, eserine, cocaine, argyrol, fluorescein, and so forth—can be used in conjunction with penicillin.

Penicillin has no effect on body tissues; there is no inhibiting effect on leukocytes; it is less lethal than the sulfonamides; secretion and debris do not inhibit its ac-

tivity; on the other hand, it seems that the more pus and organisms present, the more striking is the effect of the penicillin.

Toxic manifestations,¹⁵ local and systemic, are encountered in the use of penicillin, and have been variously reported as chills, fever, headaches, eosinophilia, urticaria, thrombophlebitis, gastrointestinal reactions, serum sickness¹⁶ of varying degree, contact, vesicular, and bullous dermatitis, swelling of the conjunctiva and eyelids.¹⁷ However, these reactions are not as frequent nor as severe as those associated with the use of the sulfonamides, and promptly disappear when the administration of the drug is discontinued.

In cases of episcleritis, phlyctenular keratitis, marginal ulcerations, herpetic keratitis, and corneal ulcerations in general, penicillin has no value unless there is an associated infection with a susceptible organism. It is not too effective when administered intramuscularly in the case of deep ocular infections due to the difficulty in obtaining sufficient concentration in the ocular tissues, and to the inability of the penicillin to penetrate into the intraocular spaces. It is best used early before deep infections occur but, with the advance of time, intraocular injections will become feasible.

Very recently, Stokes and others,¹⁸ after a very exhaustive study of the use of penicillin injections for neurosyphilis, stated that "the results in primary optic atrophy are as yet inconclusive."

When used locally, penicillin must be kept in constant contact with the tissues either by way of the ointment, frequent instillations of the aqueous solution, continued corneal baths, or by iontophoresis.

It has been used as a subconjunctival and anterior-chamber injection, with good results if a pure solution was used, but it should be injected in small quantities. Injection into the vitreous of a very pure solution has been advocated with caution.

Penicillin has little, if any, value in choroiditis of unknown etiology, and one must question the few reports which attempt to show that results have been obtained.

Recently, Ida Mann¹⁹ reported the intraocular use of penicillin in 29 cases of severe infection following injury. Only those cases were chosen in which, from general clinical experience, the prognosis was considered to be hopeless; namely, unless enucleation was performed the pathologic process was expected to continue indefinitely. In these cases, 0.25 c.c. of a solution of 1,000 to 50,000 units was injected into the anterior chamber or vitreous; penicillin ointment was applied locally. The weaker dilutions seemed to give the best results, and the stronger solutions were used only in the most desperate cases. The prognosis was worse, if the lens had been injured. Where the penicillin came in direct contact with the vitreous, the vitreous became opaque, and sight was not regained. In all cases which recovered, there occurred a reactive iritis lasting four days but subsiding suddenly. Apparently, only two injections were necessary, and in all cases where a third injection was deemed necessary, the eyes remained blind.

Of these 29 cases, 11 eyes did not improve and were enucleated. Of the remaining 18 eyes, nine healed and remained quiet and painless, but blind from damage done by the original injury. In three of these, the injection was made into the vitreous, which became opaque and did not clear; one healed with cataract formation; one regained 6/200 vision; one regained 20/100 vision; and the remaining six healed with good results.

In the experimental work on rabbit eyes, which preceded this clinical trial, penicillin injected into the anterior chamber produced a reactive, aseptic, anterior uveitis of varying severity, with 100 per-

cent pure solution producing a minimal reaction. When injected into the vitreous, it produced a most complete neuroretinal degeneration followed by fibrosis, and accompanied by thickening and fibrosis of the choroid. Again, pure penicillin showed minimal and transitory effects, or none at all.

It appears, therefore, that intraocular injections of penicillin, while at present subject to great caution, may ultimately prove of tremendous value in combating intraocular infections. When used locally after operations, or at once in penetrating injuries, penicillin prevents the incurrence of infection, and will readily disinfect the conjunctival sac prior to ocular surgery.

It is important that solutions for topical application be frequently and carefully prepared, and properly refrigerated. It must be frequently applied to maintain concentration. The ointment, 1,000 Oxford units per gram, is admirable because the penicillin retains its activity in high concentration for a longer period of time. As in the case of the sulfonamides, penicillin must be continued for at least 48 hours or more after apparent clinical cure to prevent a relapse.

With the apparatus of MacMillan of the physiotherapy department of the Royal Victoria Hospital, Montreal, iontophoresis²⁰ produces the quickest and most effective penetration of penicillin into the anterior chamber of the eye, and is followed by excellent results in bacterial infections of the anterior segment. However, the apparatus is not readily available, and the technique requires considerable care and attention. A continuous corneal bath or a continuous drip method while the patient is awake, or the method of Wright,²¹ where a pipette is inserted under the inner end of the upper lid while the patient is asleep, are excellent and more simple methods to employ. The subconjunctival injection of penicil-

lin will also result in a penetration of the drug into the anterior chamber. In addition, edema or inflammation of the cornea, cocainization of the cornea, or damage to the corneal epithelium will increase the rate and amount of penetration.²²⁻²⁵

Very little has been written about penicillin control of sympathetic ophthalmia.²⁴ Gamble²⁶ gave his patient, previously mentioned here, large doses of penicillin after he became toxic to the sulfonamides, and five months after the onset of sympathetic symptoms, with no penicillin for the past four months, no cells have been noted in the anterior chamber, and the vision remains normal, although several attacks of ciliary irritation have occurred.

Another case, which I believe responded to penicillin, suffered a laceration of the eyeball with a safety razor blade. Apparently, because of continuous inflammatory reaction for six weeks after injury, an enucleation was performed. Four days later the patient came under my observation. Intuition prompted a daily slitlamp examination. Only an occasional cell was noted in the anterior chamber, but within the next four days the cells increased in such numbers that sulfathiazole was promptly administered. The same evening the patient had severe hyperpyrexia with a rash and acute gastroenteritis. The sulfa was immediately discontinued—followed by prompt relief of the toxic symptoms. The following day the cells increased in number. The patient was given 30,000 units of penicillin intramuscularly every three hours around the clock. The cells in the anterior chamber became very numerous and large deposits formed on the posterior surface of the cornea. Within five days after penicillin therapy was instituted, the cells began to diminish, the deposits gradually decreased in size and number and, after 15 days, no further activity was noted, ophthalmoscopic examination was entirely

negative, and the vision was normal. The penicillin was administered for a total of 21 days. The patient was observed for about two months, was examined one year later, and continued to be free of all symptoms with no recurrences. It would appear that penicillin certainly merits a trial in similar instances. It should be noted that the penicillin was started very early. I might add that the daily slitlamp examinations revealed the activity, prior to any subjective or other objective symptoms, and these were minimal even after they did occur, possibly because of the concurrent penicillin injections.

The clinical evidence for the use of penicillin is overwhelmingly in favor of its local application to the lids and to the conjunctival sac. It is specific for almost all types of infectious conjunctivitis and blepharitis, which respond best to the ointment.

In ophthalmia neonatorum and gonorrheal ophthalmia,³⁰ penicillin acts miraculously in aqueous solution, being advocated in strengths of 200 to 1,000 units per c.c., applied locally. The British²⁷ had suggested its use locally. In 1943, we²⁸ saw a most terrific discharging gonococcal ophthalmia of two weeks' duration. Since penicillin was not readily available to us at the time, we drained the bottoms of several vials and made up a saline solution of 500 units per c.c. and instilled it hourly. When a clinical cure was obtained in 24 hours, it was believed that the solution was too strong, and it was reduced to 250 units per c.c. Our later experience indicated that either 500 or 1,000 units per c.c., made up fresh every few days and kept properly refrigerated, is the solution of choice, with a complete cure to be expected in one or two days.

Sorsby²⁴ advocates the use in infants of one drop at intervals of one minute for a half hour. He says that drops every

hour are good, but every five minutes, better.

When a genital gonorrhea coexists, the intramuscular injections²⁹ will also control the ocular infection; nevertheless, we believe that, in addition, a solution of penicillin should also be instilled locally. However, when there is no other lesion present, except in the conjunctiva, local instillations will suffice, and, under these circumstances, intramuscular injections are not indicated unless the local treatment should happen to fail.

The specificity of penicillin for the gonococcus also brings up the question of a substitute for the present recognized form of Credé prophylaxis, and it is possible that, in the near future, either penicillin solution or ointment may be found more efficacious and less irritating than 1-percent silver nitrate.

We advocate¹⁷ the use of the weaker solution for irrigation of the lacrimal sac in instances of acute suppurative dacryocystitis, and we have found that it will prevent infection when used as irrigation through the puncta after dacryocystorhinostomy.

It must be remembered that in cases of orbital cellulitis, where an abscess develops and presents a fluctuating localization, penicillin injections alone are not sufficient. Proper incision and drainage are absolutely essential, after which penicillin packs or frequent local irrigations through the surgical incision, in addition to the injections, result in rapid recovery.¹⁷

In considering the value of penicillin in ocular therapy, one is aware of an absence of agreement among observers, and discrepancies are reported in the clinical results obtained, but these are probably due to impurities of the products available. As our knowledge of penicillin grows, and when a really pure product

is produced or an effective synthetic product is developed, we can anticipate more certain results and possibly even more rapid and spectacular cures.

This statement can be supplemented by quoting a report by the United States Public Health Service and National Institute of Health:³¹

"Penicillin, as commercially prepared, contained not one but several penicillins, known as G, X, F, and K. Penicillin K has been shown to be of little or no value in syphilis and in certain other infections because, as compared with other penicillins, it is rapidly destroyed in the body. The relative effectiveness of the other penicillins G, X, F has not yet been determined for syphilis or for other infections. . . . The situation as to penicillin is a complicated scientific problem under co-operative study both in laboratories and in clinics."

Recapitulating this discussion we can say that: (1) penicillin is the most effective therapeutic agent for acute superficial bacterial infections of the eye; (2) it has great value as a prophylactic before surgery or after injuries; (3) it is indicated in nonbacterial infections only if secondary bacterial infection is present or threatened; (4) in intraocular infections bacterial in origin, it must be used in frequent and continuous intramuscular injections of high concentration in conjunction with high local concentration.

THE HYPERTHERM

There is nothing new about heat treatment, this form of energy having had therapeutic application since the early days of human existence. Foreign-protein injections, intravenous, subcutaneous, and intramuscularly, may produce fever, and they have been used by everyone in many cases, but here also there are limitations to their application.

Hyperpyrexia has now been modernized in the form of the feverbox or hypertherm; it has been popularized and used extensively in other branches of medicine, and a few ophthalmologists have been sufficiently interested to publish their results with this method.^{33,34,35} The hypertherm was used in a series of 14 cases in which there were pathologic conditions present in 18 eyes. These were not usual nor routine cases. They were cases of a more or less serious nature in which either typhoid vaccine, intravenously, was believed contraindicated, or in which its use had proved unsatisfactory or dangerous because of unfavorable reactions. Other types of injection might have been tried, but the pathologic process was too active to warrant taking a chance with any type of therapy which would show results only after a prolonged period of administration. Except for the usual local treatment, which was carried out in each case, there was nothing else which could be used to stem the active pathologic process. The sulfonamides were disregarded because our previous experience with their use in similar cases was very discouraging.

The ability to keep the body temperature at a desired level, for a specific length of time, is a distinct advantage, and it is believed that these factors play an important role in the therapeutic successes obtained. Except for the discomfort of the treatment itself, there were no unfavorable reactions, either local or systemic. Without exception, those patients who were suffering pain voluntarily stated that the pain disappeared during the fever session. All the usual local treatments such as fomentations, atropine, dionin, and so forth, were continued either during or between sessions.

Stated briefly, patients must be prepared for the hypertherm treatments psychologically and physically.³² The heart,

kidneys, blood, and chest must be relatively normal. The afternoon before the treatment, salt must be given orally and intravenously, plus a cleansing enema; a mild sedative is given both the night before and the next morning, one hour before entering the feverbox. During sessions, the specific gravity of the blood is determined and saline is administered by mouth and intravenously.

The temperature of the treatments varied between 102.5 and 105 degrees. Although Smith³³ recommends 105 degrees for a two-hour period and Knight³⁴ advises 105 degrees for a five-hour period, our observations indicated that better clinical results and better coöperation resulted from a moderate 103-degree fever sustained for a period of four to five hours. It should be stated that it requires from one to two hours to raise the patient's temperature gradually to the desired level. It is during these two hours that the patient is most apprehensive and requires the greatest amount of attention. In our series the fever sessions were repeated every two to five days; two patients receiving 5 treatments each, and two patients receiving 12 treatments each, with an average of 9 treatments per patient. The length, frequency, and severity of the treatment depended upon the pathologic condition present and upon the ability of the patients to withstand the treatment. This entire procedure should be under the supervision of a physician physiotherapist with whom there must be mutual coöperation. I am sure that the success we have had was in no small part due to the genuine interest and coöperation of my colleague, Dr. L. S. Shensa.

The pathologic conditions present in the 18 eyes were classified as: choroiditis, 5; iridocyclitis, 5; uveitis, 4; corneal abscess, 2; and severe interstitial keratitis, 2 eyes, both in the same patient with a positive Kahn reaction but no other evi-

dence of congenital syphilis. The visual results were excellent in 8; good in 4; fair in 3; and poor in 3.

A therapeutic success occurred in all the cases. The pathologic activity ceased, and no further local or systemic treatments were necessary except in the case of a colored patient with bilateral sarcoid uveitis who regained fair vision with marked reduction in the pathologic activity but who, later, suffered a recurrence of the uveitis. The hypertherm treatments were not repeated because we believed that the patient could not tolerate them. The three eyes in which poor vision resulted included one with uveitis and two with corneal abscess. Each of these abscesses involved three fourths of the cornea and, because of imminent perforation in both cases, paracentesis was performed, and the corneal section was opened twice on successive days.

We must consider the possibilities of future recurrences in some of these cases; nevertheless, without this type of therapy, it seems certain that the pathologic activity in these eyes would have continued indefinitely and would have resulted in an enucleation in at least some of the cases; and, certainly, blindness would have resulted in many of the 13 remaining eyes.

Ophthalmologists have given the hypertherm scant attention and, in general, are not aware of the usefulness of this very valuable adjunct to their therapeutic armamentarium. It is, therefore, my desire to bring this form of therapy to your attention and to urge its more frequent use in specific cases.

In conclusion, I would like to state that before long, much that we have said may become obsolete—new drugs and new methods of application will be developed. It was not my desire to give a complete review of the subject, but rather to present a general review of the situation, and to encourage an impartial interpretation

of the information which is being published. Chemotherapy and the hypertherm offer excellent and successful results in certain types of ocular conditions, and they are worthy of a trial in many others.

Therapeutic success depends upon the

doctor's ability to analyze each individual case and to decide, quickly and accurately, which form of therapy will achieve the best results, with relief from suffering and with preservation of vision.

INFLUENCE OF PENICILLIN ON THE COURSE OF OCULAR LESIONS DUE TO A TOXIC AGENT*

IRVING H. LEOPOLD, M.D., AND WILLIAM O. LAMOTTE, JR., M.D.
Philadelphia

Penicillin has been shown experimentally^{1,2} and clinically^{3,4} to be an effective local agent in the treatment of corneal infections due to penicillin-susceptible organisms. However, there is little reported evidence in the open literature of the value of local penicillin in the prevention of secondary infection in corneal lesions due to toxic agents. It, therefore, seemed advisable to present some data on the course of an experimental standardized ocular lesion, due to vesicant agents, that was treated with penicillin.

METHOD

Six rabbits were used, and organisms from the corneal surface of both eyes

lowed to close immediately after the application had been made. Each eye was read daily and numerically evaluated by a method previously described.⁶

Twenty-four hours after burning, material for cultures was again taken from the corneal surface, following which penicillin, in dosage of five drops of a solution containing 250 units per c.c., was applied to the right eye, and sterile normal saline, in similar quantity, was applied to the left eye of each rabbit. Such therapy was repeated at 9, 11, 1, 3, 5, and 7 o'clock each day. Cultures were taken of the treated and control eyes every day at 8:45 a.m., so that there was a lull in therapy for 13 hours prior to culturing.

TABLE 1
ONSET OF CORNEAL VASCULARIZATION

Controls	O.S	5	1						

of each rabbit were removed with a platinum loop for culture 24 hours before and immediately after burning.[†] Free-base[‡] HN₂ (0.4 mg.) was applied to the superior limbus of each eye from a Mc-Masters microsyringe,⁵ and the lids al-

These eyes were read daily for 21 days. At the end of this time, photographs were taken, and the eyes were enucleated, prepared by celloidin technique, and stained with hemotoxylin and eosin. All eyes were marked so that sections were cut through the most severely involved area of each cornea. Microphotographs were taken of that portion of each corneal section which demonstrated the most histologic change.

* From the Department of Ophthalmology of the University of Pennsylvania Hospital. The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the University of Pennsylvania.

† Cultures were first run on blood-agar plates, aerobically and anaerobically. Differentiation media were used as required. All plates were read at 24- and 48-hour intervals after culturing.

‡ HN₂—a symbol representing a nitrogen mustard (dichlorodiethyl ethylamine).

CLINICAL RESULTS

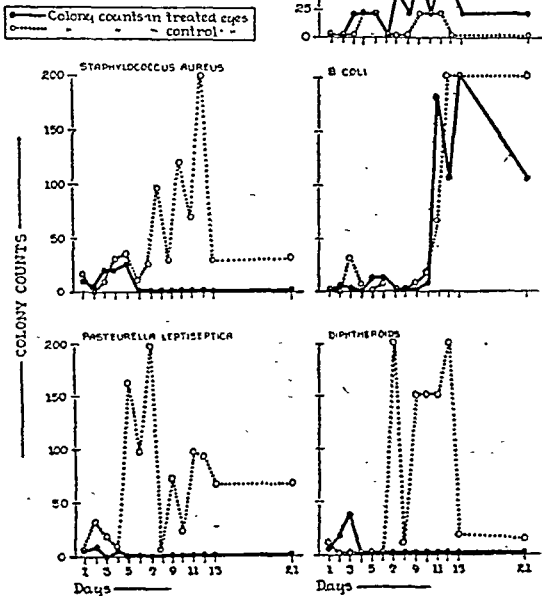

Clinically, all the eyes treated with penicillin solution showed decidedly less conjunctival discharge, edema, and injection than the control eyes. Four of the

Influence of Locally Applied Penicillin on Course of Ocular Lesions due to Nitrogen Mustard

Graph 1 (Leopold and LaMotte)

Bacterial Flora of Nitrogen Mustard Contaminated Eyes as Influenced by LOCAL PENICILLIN

Graph 2 (Leopold and LaMotte)

six treated eyes showed slightly less corneal edema when examined with a biomicroscope and compared to the control. The onset of corneal vascularization was significantly delayed in the treated eyes as is seen in Table 1.

No significant difference could be noted in the rate of corneal epithelial regeneration. By the end of the 21-day period, there was a well-defined inequality in the severity of the total lesion between the treated and the untreated eyes of four rabbits. In two rabbits, the contrast was not significantly evident. When the clinical evaluations are compared through mean and standard deviations and plotted graphically, it is evident that a wide separation of the mean values occurs, but the standard deviations do not quite separate (graph 1).

BACTERIOLOGIC RESULTS

The organisms found were staphylococcus aureus, proteus vulgaris, diphtheroids, bacteria coli, pasteurella leptiseptica, an occasional beta-hemolytic streptococcus, neisseria sicca, and neis-

usually increased in number (graph 2). It was also evident that the growth of organisms, as in mustard ocular lesions, gradually increased and reached a maximum by the end of the first 7 to 10 days after burning. Graph 2 also demonstrates

Fig. 1 (Leopold and LaMotte). Clinically the treated right eye shows a clear cornea while the control cornea shows definite haze of lower third. Histologically the control cornea shows slightly greater cellular infiltration.

seria flava. Several observations were fairly evident after a study of the daily colony counts of each organism. It was noted that the nitrogen mustard did not have a significant bactericidal effect on the organisms. Only staphylococcus aureus showed a slight decrease in incidence in the 24 hours after burning. The diphtheroids and the pasteurella organisms ac-

the striking influence of locally applied penicillin on the bacterial contamination of the conjunctival cul-de-sac following nitrogen-mustard burns. In the case of three organisms sensitive to penicillin, the penicillin-treated eyes no longer showed these organisms after three to four days of local therapy. This can easily be seen by examining Graph 2 with particular ref-

erence to the staphylococcus aureus, the pasteurella leptiseptica, and the diphtheroids; whereas, the organisms not sensitive to penicillin—such as proteus

described.^{7, 8, 9} The eyes of this series do not differ from those previously described except in two details: (1) The treated eyes of four rabbits showed significantly

Fig. 2 (Leopold and LaMotte). The left cornea shows greater opacification, vascularization, cellular infiltration, and edema than the treated right cornea.

vulgaris and bacteria coli—continued to flourish in spite of therapy.

HISTOLOGIC RESULTS

The histologic course of a severe nitrogen-mustard burn has been adequately

less inflammatory cell infiltration of the corneal stroma than the untreated eyes. (2) Less corneal edema occurred in the treated eyes of the same four rabbits.

There was less inflammatory cell invasion of the anterior chamber in the

treated eyes of three rabbits, but this was not as striking as the reduction of corneal cellular infiltration.

corneal section showing the most histologic change. It is evident that in four rabbits the control cornea shows more

Fig. 3 (Leopold and LaMotte). The treated cornea shows decidedly less edema and cellular infiltration than the control but still shows considerable disturbance of the normal corneal structure.

The accompanying photographs show the treated and untreated eyes of all six rabbits after 21 days. The corneal microphotographs were taken at a magnification of $150\times$ through the portion of the

cellular infiltration and detritus than the treated cornea.

DISCUSSION

It is evident from these data that local penicillin therapy has a beneficial influ-

ence on the course of ocular burns due to liquid free-base nitrogen mustard. It is also fair to assume that, if all organisms had been sensitive to penicillin and, if animal resistance against infection did

in ocular burns due to mustard gas, and the influence of chemotherapeutic agents on the course of such lesions has been studied.^{10, 11} The data indicate that local sulfonamide therapy and local penicillin

Fig. 4 (Leopold and LaMotte). The left cornea has almost perforated and the cellular infiltration is massive. The right eye shows decidedly less edema. Although the infiltration is less than in the control cornea, it is still marked.

not vary from animal to animal, the effect would have been even more striking. It is not necessary to point out that such treatment does not cure a severe splash-and-blink burn but simply decreases its intensity.

The significance of secondary infection

therapy, even more so, will reduce conjunctival discharge, bacterial flora, resulting lid deformities, delay the onset of corneal vascularization and, to a small degree, even reduce the amount of corneal edema. Histologic evidence of secondary infection has been demonstrated by

Hughes¹² to occur in lewisite-burned corneas and by Scholz¹³ to occur in nitrogen-mustard-burned corneas. Considerable

CONCLUSIONS

1. Local therapy with penicillin solution reduces the conjunctival discharge,

Fig. 5 (Leopold and LaMotte). The control cornea shows a severe corneal ulceration, cellular infiltration, cellular collection on posterior surface, and marked thickening. The treated cornea shows superficial infiltration.

evidence has thus accumulated that demonstrates the value of anti-infectious agents for the prevention of secondary infection in corneas previously damaged by a toxic chemical.

edema, and injection, delays the onset of corneal vascularization, and decreases slightly the amount of corneal edema of ocular lesions due to liquid free-base nitrogen mustard.

Fig. 6 (Leopold and LaMotte). Both corneas show opacification and edema to almost the same degree. The control eye shows slightly more cellular infiltration.

2. Local penicillin therapy decreases the bacterial flora in nitrogen-mustard ocular lesions.

3. The most marked histologic changes

altered by local penicillin therapy in nitrogen-mustard ocular lesions were the reduction in amount of corneal inflammatory cell infiltration and corneal edema.

REGARDING GONIOPHOTOGRAPHY

RAÚL RODRIGUEZ BARRIOS, M.D., AND
ROBERTO VAZQUEZ BARRIERRE, M.D.
Montevideo, Uruguay

The technique proposed by Goldman for the study of the anterior-chamber angle has, doubtlessly, been simplified for daily application in the clinic.

This investigator has devised a contact lens provided with an inclined mirror that reflects the image of the angle of the anterior chamber for study with the slitlamp; by rotating the lens the angle can be studied in its entirety.

This procedure offers the advantage of permitting extensive studies, with the patient and the ophthalmologist comfortably seated as when making an examination with the slitlamp. In addition, it has the advantage of permitting the study of the angle with slits of variable widths; according to Busacca, when narrow beams of light are used, optical sections of the angle of the anterior chamber are observable, revealing its form with precision.

We have used Goldman's contact lens and Haag-Streit's slitlamp to obtain goniophotographs. For this purpose, as shown by figure 1, in place of one of the

Fig. 1 (Barrios and Barriere). A Leica camera is inserted in place of one of the oculars of the corneal microscope.

Figs. 2, 3, and 4 (Barrios and Barriere). Different aspects obtained when wide or narrow slits are used.

Fig. 5 (Barrios and Barrierre). An eye with a dilated pupil.

oculars of the corneal microscope, a Leica camera provided with Leica's microscopic device is inserted. This device has a lateral visor which permits the exact focusing of the part to be photographed.

The procedure is carried out as follows:

The usual steps for studying the angle are taken; then, the Leica, with the micro-Leica in place of one of the oculars, is adjusted. Upon looking through the lateral visor, it will be seen that it has a reticule, the lines of which are sharp and definite when focusing with the lens on this lateral visor.

The first step, therefore, is to focus exactly the lens of the lateral visor so that the lines are sharp and clear. Then, with the micrometer, the part that is to be photographed is focused. The Leica must be kept "open" and, through a double release, the following manipulations are obtained: (1) the closing of the lateral visor, and (2) the opening of the diaphragm which permits a variable opening according to the requirements of the case.

In our cases, with Plus-X films, we give 0.5- and 1-second exposures. Unfortunately, we have not been able to obtain color films for artificial light. We believe that with such films it would be possible to obtain far more exact photographs, since these would clearly show the different colors observed in the region.

The accompanying illustrations show the different aspects obtained when wide or narrow slits are used. In taking figure 2, the slit was entirely open. To interpret these photos, it is necessary to remember that an image is obtained in the mirror on the opposite side of the angle. In the case of figure 2, one sees the pupil and, underneath it, a horizontal line (B) corresponding to the limit of the mirror. The opposite angle of the anterior chamber is also reflected (A) which appears as an inclined plane, because that is the position occupied by the reflecting surface. Underneath is a series of lines of little importance because they are merely reflexes in the limit of the contact lens. In figure 3, the slit was narrower, and in figure 4, still narrower. It is possible to narrow it more, but the resulting photograph is not so clear.

As can be appreciated, the narrow slit permits following the faces of the angles and gives us a good impression of depth,

Fig. 6 (Barrios and Barrierre). Same eye as in figure 5 photographed with a narrow slit.

Figs. 7-10 (Barrios and Barriere). Fig. 7, Photograph with ample angle in which sense of depth is evident. Fig. 8, A case of traumatic iridodialysis. Fig. 9, An antiglaucomatous iridectomy. Fig. 10, This shows the gap opened by the cyclodialysis in a case of essential atrophy of the iris.

not obtainable with the wide slit. It permits, in addition, the comparison of the different angles and their classification according to width. Figure 5 shows an eye with dilated pupil. The folds of the roof of the iris can be clearly seen; these are formed by the dilatation. The arrow shows Schwalbe's line, and, exactly in the angle, a pigmentary nevus can be observed.

Figure 6 is of the same eye, but obtained with a narrow slit. The nevus and Schwalbe's line can be observed, as indicated by the arrows.

Figure 7 is a photograph with ample angle, and all the details are clearly defined; the sense of depth is evident.

Figure 8 corresponds to a case of trau-

matic iridodialysis. The pupil can be seen, and, at the right, the dialysis zone. In the inferior part is seen, reflected in the mirror, the superior part of the angle of the anterior chamber. The details of the iris can be clearly seen. With this procedure, excellent photographs of the iris can be obtained. Figure 9 corresponds to an antiglaucomatous iridectomy. Finally, figure 10 shows the gap opened by the cyclodialysis in a case of essential atrophy of the iris.

We believe that the perfection of this technique, and especially with the use of color films, will place this procedure among the most useful for goniophotography.

NOTES, CASES, INSTRUMENTS

RETINOBLASTOMA*

AN UNUSUAL CASE

ALBERT N. LEMOINE, JR., M.D.
Boston, Massachusetts

It is hoped that by reporting the following case, a similar error in diagnosis and treatment may be avoided by others. This case also serves as a warning against the use of vitreous injections of penicillin in cases of obscure intraocular infections.

A review of the ophthalmic journals since 1925 failed to reveal a similar case. Other cases of mistaken diagnosis were reported, but none had a clinical picture as found in this patient.

The case history is presented in detail because: (1) the physical and laboratory findings, even in retrospection, easily lead to an incorrect diagnosis; and because (2) the patient was subjected to extensive surgical and X-ray procedures which were futile

CASE REPORT

P. W., a 3½-year-old boy, was first seen in the Eye Out-Patient Department of the Massachusetts Eye and Ear Infirmary on February 26, 1945, complaining of a red eye and questionable pain of five days' duration.

Three weeks before admission, according to the mother, the boy was hit in his right eye with a stick. His eye was not inflamed, nor did he complain of pain until five days before admission. At that time, his right eye became slightly inflamed, and he complained of a headache during the night. About this same time, the mother noted a "queer" appearance in the pupil of the right eye. The child's general health had been excellent with no recent illness.

* From the Massachusetts Eye and Ear Infirmary, Howe Laboratory of Ophthalmology.

Examination. The right eye was slightly injected. The cornea was clear with no evidence of recent nor old perforation. The anterior chamber was clear and of normal depth. The iris was normal, but the pupil was slightly dilated. The pupil did not react directly or consensually to light. Behind the lens there was a uniform, yellowish reflex that was structureless and appeared to be an exudate. The tactile tension was normal. Vision was nil. The left eye was entirely normal with a good red reflex.

Diagnosis. Metastatic endophthalmitis of the right eye was the diagnosis made.

On the same day, February 26th, the child was admitted to the Hospital for a complete medical work-up. The physical examination, X-ray pictures of the sinuses and chest, Hinton and tuberculin tests were all negative. On February 28th, the right eye was moderately injected, but otherwise was the same as on admission.

Because the "inflammatory" process appeared to be more active, the child was taken to the operating room on March 2d and, under ether anesthesia, a needle was inserted into the vitreous. Approximately 0.5 c.c. of creamy, yellow material was aspirated and 8,000 units of penicillin were injected into the vitreous. The aspirated material was sent to the laboratory for culture and identification.

On March 5th, the child was discharged with a diagnosis of vitreous abscess. The culture of the aspirated material revealed alpha hemolytic streptococcus, beta hemolytic streptococcus, and coagulase positive hemolytic staphylococcus. No focus for the intraocular infection had been found.

A week later, the child was seen in the Clinic, and the right eye was white and quiet. The fundus reflex was still yellow. No structure was visible to the vitreous

mass. On March 26th, the right eye was white and quiet, but the fundus reflex was now becoming gray. There was no visible structure to the material in the vitreous. On April 21, 1945, the right eye was slightly injected. The pupil was still dilated and did not react to light. The iris was now beginning to vascularize.

Four days after this, the child was brought to the clinic complaining of nausea and severe pain over the right side of his head. The eye was injected, and there were numerous new vessels on the iris, with early iris atrophy. The fundus reflex was gray, and there was no visible structure. The tactile tension was normal. The child was given aspirin and no local treatment.

On July 2d, the child returned to the clinic because the right eye had repeatedly "flared up." On this day, the eye was white, and the child did not complain of pain. The iris was atrophic and covered with new vessels. The pupil was moderately dilated and the fundus reflex was gray. There was no visible structure to the vitreous mass.

The child returned to the clinic on July 7th, because the right eye had become red and painful. He was admitted to the Hospital for enucleation of the right eye. On admission to the Hospital, the right eye was moderately injected. The cornea and aqueous were clear. The iris was atrophic and had numerous dilated vessels on the surface. The pupil was moderately dilated and did not react to light. The fundus reflex was gray-yellow, and no structure was visible. The tactile tension was normal. On the afternoon of admission, the right eye was enucleated. The child had an uneventful recovery, and was discharged on the fifth postoperative day.

On August 28th, the child returned to the Nose and Throat Clinic complaining of nasal discharge. X-ray studies of the sinuses revealed increased density in the

right maxillary sinus and the right ethmoid region. He was admitted to the Hospital, given intramuscular penicillin, had an uneventful recovery, and was discharged 14 days later. In the meantime, the right socket had healed completely.

The child returned to the Eye Clinic for a routine check-up the first day of October. The pathologic report on the right eye was returned with a microscopic diagnosis of retinoblastoma that had invaded the optic nerve to the cut end. When the eye was opened, the vitreous was filled with homogenous, gray-yellow, structureless debris; and the gross pathologic diagnosis was vitreous abscess. It was only after the routine microscopic examination that the diagnosis of retinoblastoma had been made.

X-ray films of the head, chest, and pelvis were all negative for metastases. Complete physical examination for evidence of metastasis was also negative. On the basis of these negative findings, the child was admitted to the Hospital for exenteration of the right orbit.

On October 2d, under ether anesthesia, an exenteration of the right orbit was performed. The lids and orbital contents were all removed by block dissection. The patient had an uneventful postoperative course, and was discharged on November 2d. Two days before discharge, the microscopic report on the optic nerve removed during the exenteration was returned. The optic nerve was found to contain tumor tissue up to the cut end at the optic foramen. This tumor tissue apparently had not invaded the surrounding tissue and appeared to be confined to the optic nerve only. X-ray films were again taken and were found to be negative for metastases. On November 5th, examination showed the socket to be granulating in very well.

Three days later, the child returned to the Nerve Out-Patient Clinic of the Mas-

sachusetts General Hospital, where a complete neurologic examination failed to reveal any evidence of metastatic lesions. The child was given an appointment for admission to the Massachusetts General Hospital for a right frontal craniotomy and removal of the right optic nerve up to the chiasm. He was admitted to the Massachusetts General Hospital on November 13th. Complete physical, neurologic, and X-ray examinations were negative for metastatic tumor. The next day, under intra-tracheal gas-oxygen-ether anesthesia, a right frontal exposure was made. The right frontal lobe was retracted and the right optic nerve was exposed. There was questionable enlargement of the right optic nerve. The right optic nerve was severed at the chiasm and removed in block dissection. No abnormal tissue was noted in the area.

On December 6th, the child was seen in the Nerve Out-Patient Department where all surgical wounds were found to be well healed. According to the patient's mother, the child had been vomiting after each meal for about three days. When the child was seen in the Eye Out-Patient Department on December 27th, the socket was well healed. There were three firm, painless lumps about the size of duck's eggs on the right forehead. The mother stated that these lumps first appeared three weeks earlier and had rapidly increased in size. The patient was still vomiting after meals and complained of pain over the right frontal area. He was admitted to the Massachusetts General Hospital for deep X-ray therapy. Physical examination on admission revealed multiple, painless nodules over the right forehead and vertex. X-ray films revealed destruction of the paper plate of the ethmoids on the right side, with loss of the entire lower and inner orbital rim. The destruction also involved the right frontal bone and sinus. Other X-ray films were negative for metastatic lesions.

Deep X-ray therapy was started the next day. During the following 17 days, he was given a total of 2,900 R. units through a single portal covering the right orbit and forehead; and 1,900 R. units were applied to the vertex lesion. The 2,900 R. units were given with the 1,200 K. V. X-ray machine in doses of 300 R. units per day; while the 1,900 R. units were given with the 200 K. V. X-ray machine, 300 R. units per day.

Despite the above heavy doses of X ray, the superficial lesions increased rapidly in size, and the orbital cavity became filled with new nodules. The child became progressively drowsy, lost weight, and vomited all feedings. He was discharged on January 15, 1946, because further therapy was deemed hopeless.

On February 26th, the child died at home. According to the mother, during the last two weeks of life the nodules became much larger, the child became more irritable and irrational, and he suffered severe pain. Unfortunately, no autopsy was performed to determine the extent of the metastases.

SUMMARY

In summarizing this case, the following features appear important:

1. The clinical picture of a homogeneous, yellow, avascular mass floating in the vitreous, typical of a vitreous abscess, proved to be necrotic tumor tissue.

2. The culture of the aspirated vitreous material revealed three pathogenic organisms which are difficult to explain on the basis of contamination. This culture, together with the clinical picture, resulted in the incorrect diagnosis of vitreous abscess.

3. The gross examination of the globe, following enucleation, failed to reveal the presence of the retinoblastoma. The correct diagnosis was made only after routine histologic examination.

4. The extensive surgical procedures of

exenteration and craniotomy failed to prevent a fatal outcome, although they seemed justified at the time as the only hope.

CONCLUSIONS

This case illustrates an error in diagnosis that resulted in death from retinoblastoma. With the widespread use of penicillin in ophthalmology, it serves as a warning against the use of vitreous injections of penicillin in suspected infections unless the diagnosis is certain.

This case also lends support to the belief that irritable or painful blind eyes should be enucleated and subjected to detailed histologic examination.

In cases of retinoblastoma with definite extension in the optic nerve and no evidence of metastasis, extensive surgical procedures must be carried out with a very guarded prognosis.

The failure of superficial metastatic nodules to respond to a large dose of deep X-ray therapy illustrates the relative resistance of some retinoblastomas to this type of treatment.

243 Charles Street (14).

SPONTANEOUS CYST OF THE IRIS*

JOSEPH LAVAL, M.D.
New York

HISTORY

L. P., a man aged 57 years, had had the right kidney removed in May, 1930, for hypernephroma, confirmed on pathologic examination. There were no bone nor visceral metastases at that time. In January, 1944, a mass the size of a grapefruit was noticed in the right flank. It was very firm, hard, and attached to the crest of the ilium. The patient said it had grown slowly for the past four years. On Janu-

ary 18, 1945, he came to Dr. Frey's Clinic with the complaint of a red, painful eye of two weeks' duration. There was no history of trauma.

Examination. The right eye was normal in all respects with normal vision with correction. The left eye had moderate

Fig. 1 (Laval). A large cyst (C) has replaced the iris and occupies part of the anterior chamber. It has compressed the lens (L) where it lies in contact with it.

circumcorneal injection with an occasional cell in the aqueous. A large, pale brown, cystic mass filled the temporal half of the anterior chamber, pushing an ovaly distorted pupil nasally. It almost, but not quite, reached to the pupil. There were some blood vessels on the anterior wall of the cyst, and the whole mass transilluminated easily. The pupil could not be dilated so that the fundus and media were not examined. Vision of the left eye was finger counting at two feet and was not improved. Tension was: O.D., 20 mm. Hg (Schiotz); O.S., 25 mm. X-ray studies for metastases were negative. X-ray pictures of the orbit were also negative. The urine, blood count, and the Wassermann reaction were negative. One week after admission, the left

*From the Laboratory of the Manhattan Eye, Ear, and Throat Hospital.

eye was quiet and there was no injection of the globe; the aqueous was clear.

It was decided to enucleate the globe because of the history of hypernephroma of the kidney. Although the mass in the anterior chamber transilluminated, the possibility of a metastasis from the hypernephroma had to be considered.

Fig. 2 (Laval). Some of the pigment epithelium (P) is still present and shows areas of cystic degeneration. The endothelial membrane (E) has several layers of cells.

The use of X-ray therapy was also considered, but the final decision was that enucleation was the best thing for the patient.

PATHOLOGIC FINDINGS

The globe was normal in appearance, size, and shape. On section no gross abnormalities were noted except for the cyst in the anterior chamber.

Microscopic studies showed no abnormalities except in the anterior segment. A large, empty cavity, lined by a thin layer of tissue, replaced part of the iris. The remaining iris was deeply pigmented in the region of the anterior border layer, and crypt formation was ab-

sent. There was an increase of chromatophores throughout the stroma, and the iris blood vessels were more numerous than usual. The filtration angle was normal in this region.

On the opposite side, where the iris was missing, the usual filtration angle was entirely absent, and the ciliary body itself had an obtuse angulation. The scleral spur was present and so were the pectinate ligament and Schlemm's canal, but the fibers of the ligament were closely packed and compressed and separated from the anterior chamber by a thin, but solid, membrane. Schlemm's canal was filled with blood cells (probably a post-enucleation result, since the anterior ciliary vessels here were also blood filled). The membrane which lined the filtration angle was continuous along the cornea in contact with, but separately defined from, Descemet's membrane. It was lined with its own endothelium, and the two endothelial surfaces lay back to back. The membrane continued along the anterior face of the ciliary body and then replaced the iris which should normally have been there. It was lined with a layer of pigmented iris epithelium (although somewhat atrophic in appearance) posteriorly. As it lay in contact with the lens, some of the pigment became attached to the anterior capsule and the pressure exerted on the lens caused an indentation in its contour. At this point, the lens cortex was compressed down to the nucleus. A few vacuoles had developed in this region. As the membrane left the posterior region of the iris, it lost its pigment layer and, as it curved forward in the anterior chamber, its anterior wall consisted of endothelial cells in several layers which became compressed into a single layer where they lay in contact with the posterior corneal surface. The cyst cavity was entirely empty having lost its fluid on sec-

tioning. There was no evidence of cupping of the optic nerve head.

COMMENT

Spontaneous cysts of the iris stroma usually occur in young people under 20 years of age, but one case was reported in a man of 58. They rarely give rise to any symptoms of irritation or to glaucoma. According to Duke-Elder, only 41 cases up to the present have been recorded and accepted as spontaneous cysts without any prior trauma. There is no consensus as to whether the cyst is mesodermal or ectodermal in origin, but the fluid is secreted by the epithelial cells which line the cyst cavity. The textbooks of Collins and Mayou, Fuchs, and Duke-Elder and the *Atlas of Histopathology of the Eye* by A. Fuchs, parts one and two, have no illustrations of a case similar to the one here presented.

136 East 64th Street (21).

A SIMPLE METHOD OF REMOVING EYELASHES BY ELECTROLYSIS*

JACK S. GUYTON, M.D.
Baltimore

The root of an eyelash may be destroyed by electrolysis without causing detectable scarring. A galvanic unit such as that devised by Walker may be used for this purpose. However, few ophthalmologists have access to such a unit, and all too many patients with wild lashes are treated by simply pulling the offending lashes every few weeks. Permanent removal of these lashes by electrolysis can be extremely simple, and every ophthal-

mologist could have available the following inexpensive equipment.

SIMPLIFIED EQUIPMENT

- 1 45-volt "B" battery
- 1 6-ft. strand of insulated copper wire
- 1 22,000-ohm resistance (price = 9 cents)
- 1 hemostat
- 1 very small straight needle with a sharp point
- 1 piece of gauze

TECHNIQUE

Novocaine is injected around the offending lash. The 22,000-ohm resistance is connected to the negative pole of the "B" battery and the wire is attached to this. The other end of the wire is attached to the handle of the hemostat, and the needle is grasped with the hemostat. The ophthalmologist holds the hemostat with a piece of gauze as insulation. The patient is asked to grasp the positive pole of the "B" battery firmly between thumb and forefinger, moistened with saline. The tiny needle is then inserted alongside the offending lash down to the lash root (about 3 mm.) and held there until bubbles of hydrogen come out freely and the lash itself floats out. This usually requires from 5 to 30 seconds.

The principle involved in destroying a lash root in this simple manner is to pass a galvanic current of from 0.2 to 2.0 Ma. through the patient's body. Since the needle (cathode) inserted into the lash root is very small, a sufficient concentration of hydroxyl ions is generated around the needle tip to destroy the hair follicle. The desired amount of current is obtained with a 45 volt "B" battery and a 22,000-ohm resistance in series. The electrical resistance encountered at the contact between fingers and positive terminal of the battery usually varies be-

*From the Wilmer Ophthalmological Institute of the Johns Hopkins University and Hospital.

tween 10,000 and 100,000 ohms, and the resistance at the tip of the needle is negligible. There is no danger of obtaining too much current because this is limited to 2 Ma. by the resistance unit, even should there be almost no resistance elsewhere in the circuit. Too little current can be obtained if the positive terminal of the battery is not grasped firmly or if the fingers are not moist. The time necessary to accomplish destruction of the hair follicle varies inversely with the amount of current.

The simplified equipment listed above may be elaborated upon, if the ophthalmologist so desires, by: (1) wiring to the positive terminal of the battery a metal sheet which can be grasped by the patient's hand or strapped to his arm, (2) wiring the negative terminal directly to a needle which is insulated except for the tip, (3) insertion of an ammeter in the circuit. However, these elaborations are not at all necessary.

A MOTOR-DRIVEN OPHTHALMOTROPE

MERRILL J. REEH, COL. (MC), A.U.S.,
E. W. STIMMEL, AND F. V. HEAGAN
Randolph Field, Texas

In teaching large numbers of graduate physicians at the Army Air Forces School of Aviation Medicine, it has been found that the majority have little knowledge

concerning the normal and abnormal functions of the extraocular muscles. A small percentage possess knowledge of the function of individual muscles acting upon the globe while in the primary position, but have no understanding of movements in the secondary fields or of the conjugate function involved in the maintenance of binocular single vision. A logical understanding of heterophoria, heterotropia, and paralysis is impossible if the normal functions are vaguely or incorrectly understood.

In order to teach this branch of ophthalmology to a large group in an extremely limited period of time, a motor-driven ophthalmotrope has been constructed (figs. 1 and 2).

Each plastic globe,* 20 inches in diameter, is mounted on a movable table which is 30 by 40 inches in size. An anterior segment showing a cornea, anterior chamber, and iris has been attached to the globe proper. The inner surface of the globe has been painted white. The globe is attached to the stand by means of a ball-and-socket joint. Rotation is present about three axes; however rotation cannot be accomplished in the anterior-posterior axis with the present motor arrangement. Nevertheless, the student can

* The plastic globes were originally planned and developed by Dr. R. G. Scobee, St. Louis, Missouri, while on duty at the A.A.F. School of Aviation Medicine.

Fig. 1 (Reeh, Stimmel, and Heagan). Front view with eyes in the primary position.

Fig. 2 (Reeh, Stimmel, and Heagan). Rear view with eyes in the primary position.

Fig. 3 (Reeh, Stimmel, and Heagan). Front view with eyes rotated right and upward.

readily understand such rotation while watching the various movements of the globe. Two one-seventy-fifth h.p. motors are attached to each globe. One motor abducts and adducts, and the other elevates and depresses the globe. When acting simultaneously, both motors move the globe into an oblique position; for example, right and upward (fig. 3). The globes have been mounted on separate, movable tables so that only one need be utilized if desired. The motors attached to both globes have been synchronized so that they move together at the same rate of speed; thus demonstrating conjugate (yoke) action of muscles. Automatic stop switches act in the same capacity as check ligaments. There is a separate switch for each globe in addition to the two master switches in the main control box. This permits the operator to stop one globe during binocular rotation; thus simulating the lag which is manifested by a paralyzed muscle. The muscles have been made of red-colored elastic straps bearing the appropriate name in black letters. The elasticity thus simulates the normal muscle tonus. The superior and inferior rectus muscles produce a 25-degree angle,

Fig. 4 (Reeh, Stimmel, and Heagan). Diagram of the wiring of one globe. Wiring of both globes is identical.

and the superior and inferior oblique muscles produce a 54-degree angle, with the optical axis when the globe is in the primary position. A metal pulley acts as a trochlea for the superior oblique muscle.

By means of this apparatus, one can demonstrate the functions of the extraocular muscles when the globe is in the primary and secondary positions. The conjugate (yoke) functions can also be demonstrated, as well as the primary and secondary deviations found in various paralyses. By means of the individual control of the globes, lagging and overaction as seen in various paralyses can be simulated. In addition, this model can be used in demonstrating convergence and divergence, heterophorias, heterotropias, and the use of prisms for the measurement of vergence power.

CONCLUSIONS

A motor-driven ophthalmotrope has been developed for the purpose of demonstrating to students the normal and abnormal functions of the extraocular muscles. Such a model will be of value in the teaching of postgraduate students, medical students, and orthopticians.

DR. THEODORE L. TERRY, *presiding*

A NEW SYNTHETIC MYDRIATIC

PROF. IDA MANN of Oxford, England, wrote a paper on this subject which was read in her absence by the secretary of the Society, Dr. Merrill King. She described a new synthetic mydriatic, known experimentally by the code name, E-3, and commercially as Lachasine, which was a benzylic ester of hydroxy-ethyl-di-methyl-ethyl ammonium chloride. For experimental use, a 1-percent solution was used. When used in healthy eyes, it appeared that E-3 could be used for diagnostic and refractive purposes the same way as atropine. The reaction was more easily reversed by eserine than that of atropine. In old people, however, it is not as safe as homatropine. It appeared to lie between atropine and homatropine in its strength of action on normal eyes.

In a second group of six treatment cases, E-3 was used satisfactorily as a substitute for atropine. In a group of six patients who had had general toxic symptoms from atropine and hyoscine, it was used satisfactorily without any general symptoms and was satisfactory to the patient. In a fourth group of 42 cases, E-3 was used with striking results. All of the patients in this group had had local atropine irritation after atropine had been used for a varying length of time. Some of these patients were also sensitive to hyoscine and homatropine. All of these cases were switched to E-3; no signs of local irritation were produced; and the

previous signs of irritation from homatropine and similar drugs disappeared while E-3 was being used. With this series, it was also noted that E-3 had to be used more frequently when being substituted for atropine.

This drug can be obtained commercially from Messrs. Allen and Hanbury, Vere Street, London W, 1.

HYPERTENSIVE RETINITIS

DR. ARTHUR J. BEDELL of Albany, New York, read an interesting paper on the above subject illustrated by a large number of very fine Kodachrome slides. The instructive value of these slides came, not only from the photographs of the various changes that occur in hypertension, but also from the pictures which permitted one to observe the alterations which took place in the same patient over a long time, often years. He stressed the changes seen in the blood-vessel walls, especially the narrowing of the arteries, compression of the veins when crossed by the arteries, and atheromatous plaques in the vessel walls. He said that mere tortuosity of the blood vessels was not evidence of hypertension. He presented evidence proving that edema of the retina is present prior to the formation of the star in the macular region and that, previous to death, the star lines become broken and partially absorbed, a sign of great prognostic significance. He illustrated the various types of hemorrhages and exudates seen in patients with hypertension.

Dr. Bedell believed that many patients were symptomatically relieved by operation. The headache, especially occipital, was frequently cured, and the blood pressure often, but not always, reduced. He stated that hemorrhages and exudates

may disappear but stressed the fact that the retinal blood vessels rarely showed much improvement. The veins were more often decreased in caliber than the arteries. He had seen many patients in whom the retinal appearance was unchanged and the course of the hypertension uninfluenced.

Dr. Bedell felt that the term "transitory local constriction" of the arteries was to be preferred over "local spasm." He urged great care in describing the fundus changes to differentiate benign hypertensive retinopathy from the fulminating type.

ACTION SPECTRUM OF ULTRAVIOLET KERATITIS

DR. DAVID G. COGAN said that the present study consisted of a quantitative determination of the ultraviolet bands capable of producing an abiotic reaction in the cornea and a comparison of the radiations which produce a keratitis with those which produce erythema. For the cornea, the action spectrum was found to have a sharp peak at 288 μ which is not materially different from the corrected peak for skin. Although there is no substantial difference in the absorption spectrum and action spectrum of skin, there is a difference in the absorption spectrum of the cornea and the action spectrum of keratitis. It was concluded that the absorption spectrum of the cornea is largely determined by the nucleoprotein (peak at 265 μ), while the action spectrum is deter-

mined by a photolabile substance with absorption shifted toward the longer wave lengths (peak at 288 μ). The action spectrum of keratitis is compatible with the assumptions that the photolabile substance is either one of the cytoplasmic proteins (albumen or globulin) or a specific portion (amino acids containing phenyl rings) of the nucleoprotein.

Since ultraviolet keratitis is a common occupational hazard (for example, among welders), the transmission characteristics of various types of common glass were measured for that portion of the spectrum which is responsible for keratitis. By comparison of these characteristics with the action spectrum for keratitis, it is possible to determine the amount of protection provided by any one glass.

This study was made with the help of V. Everett Kinsey, Ph.D.

RANDOM OBSERVATIONS ON OCULAR SURGERY

DR. CECIL S. O'BRIEN read an interesting paper on the above subject. Dr. O'Brien said that morphine may be given preoperatively unless there is a wide corneal section. There is danger, of course, from vomiting. For topical anesthesia, cocaine is used, with the exception that, in glaucoma where the pupil is not to be dilated, pontocaine is used. Cocaine is also injected subconjunctivally in a 1-percent solution. Retrobulbar injection of procaine is one of the most important developments in ocular anesthesia. Akinosis of the orbicularis can be obtained by the O'Brien technique of injecting the branch of the 7th nerve. Preoperatively 5 to 20 million units of typhoid vaccine are given for prophylaxis, one or two days before the operation. Penicillin ointment is used every two hours for two days before the operation. For cataract operation, the pupil is dilated with homat-

ropine and paradrine. Dr. O'Brien believes that the axis of the section may cause the resulting cylinder axis to be off. The easy method and the type that gives less astigmatism of section is to begin with a keratome and enlarge with the scissors. The basal iridectomy is preferred because there is less loss of vitreous. He prefers modified Stallard suture with two more sutures, one on either side of the center suture. Air is injected into the anterior chamber to prevent anterior synechia and incarceration of the iris. No ointment is used in the dressing because of the danger of its getting into the anterior chamber. If both cataract and indications for glaucoma surgery are present, Dr. O'Brien prefers a cataract extraction plus a Lagrange operation.

In cyclodialysis, he believes that almost half the circumference should be done, if possible. Dr. O'Brien also feels cyclodialysis is the best operation for glaucoma when tension is slightly increased, and there is a small visual field. In aphakic cases of glaucoma cyclodialysis is the operation of choice. Gonioscopy is of value in determining the area upon which to operate.

In surgery for convergent strabismus three important factors must be taken into consideration in order to obtain maximum results: (1) Proper correction for the refractive error must be worn for at least one year; (2) effect of occlusion on amblyopia; (3) effect of proper training.

In strabismus of more than 15 degrees, he prefers a two-stage operation. First, recession of the internal rectus, and then, three or more months later, resection and advancement of external rectus. The most frequent causes of failure in strabismus surgery are: (1) poor vision in one eye; (2) inferior oblique spasm; (3) abnormal correspondence; and (4) eccentric fixation.

Dr. O'Brien stated that an adequate approach to tumors of the orbit could be obtained by doing a wide canthotomy and enlargement of the wound into the fornix. He felt the cosmetic result was better after using this method than when some of the other approaches were used.

DR. C. K. LEWIS, *presiding*

RETINOBLASTOMA

DR. E. C. ELLETT reported an unusual case of retinoblastoma. On April 13, 1944, Edward M., aged eight months, was seen. The right eye had been inflamed for two days. He had had similar mild attacks twice before. There was a history of bumping the head. The left eye was normal. The right lids were swollen and red. The conjunctiva was edematous; the cornea was normal; the aqueous, dark and cloudy; and the pupil only faintly seen. There was a tremulous look to the iris. Tension was +2. Faint reflex and faint light were present on transillumination. The condition appeared to be a contusion with hemorrhages in the eye or a metastatic ophthalmia. General examination, X-ray studies, and all laboratory tests were negative (Dr. Arthur Quin).

Sulfanilamide was ordered (2½ gr. four times a day). The eye cleared, tension seemed normal, and two small, white nodules appeared on the temporal half of the iris. The child did not seem sick and, on April 29th, the eye was white, tension normal, pupil wide, and reflex fair. The white dots on the iris remained the same.

On May 6th, the child was fretful as if in pain. The aqueous was lightly tinged with blood, and the pupil was only visible by transillumination. The eye cleared in a few days. Tension remained normal, but the aqueous was still reddish. On May 20th, the anterior chamber was full of blood, and a paracentesis was done, although the tension was normal. Much thin, bloody fluid escaped, and the eye collapsed but refilled by that afternoon.

The father, who was in service, was transferred to a post in Alabama, and the child was referred to Dr. C. A. Thigpen of Montgomery, who wrote on May 27th as follows: "Anterior chamber filled with blood, a diffuse haziness of the cornea, ciliary injection, unable to see the pupil with intense illumination, eyeball soft. The condition is certainly a very puzzling one, and I doubt very much if the fall had anything to do with it. It impressed me as being one of those rapid cases of acute uveitis, possibly, of tuberculous origin. The eye, in my opinion is doomed."

The child was seen by Dr. Anthony in August, who noted: "Right eye slightly congested. Tension, one minus. Cornea and ball look a little smaller than normal. Anterior chamber looks deep. Considerable amount of blood stain on posterior surface of cornea."

The next note was in a letter from Dr. Thigpen, September 18, 1945: "The outlook for the future of the eye was hopeless and so I advised the parents. The left eye was apparently normal so far as anyone could tell in so small a child."

"I neither saw nor heard of the case again until the early part of April this year when the parents returned saying that the child was losing the vision in the left eye. Examination disclosed a dilated pupil through which one could easily see a projecting floccular, white mass covering the entire temporal side of the retina

and extending below and across to the nasal side. This could be well seen without the ophthalmoscope. The mass was tremulous and the slitlamp showed no blood vessels. The eye was turned upward, and only a small area of the retina was sensitive and had any vision which was peripheral. There was no evidence of any inflammatory process. The tension was not above normal limits. The result of my examination convinced me that total blindness was inevitable.

"My verdict was so shocking and distressing to the parents that they hurried off to the Mayo Clinic and remained there several weeks, during which time penicillin and other remedies were used to no avail. Then, suddenly, the right eye became inflamed, followed by intense orbital cellulitis with marked exophthalmos, and removal of the eye was advised. This they decided not to do, but returned to Montgomery. I fully agreed that nothing short of enucleation could be considered. This was done today. I discovered that there had been a profuse retrobulbar hemorrhage which explained the exophthalmos. Thinking that you might be interested in the outcome of the case, I am sending you, under separate cover, the eyeball. There were so many adhesions that it was impossible to do a very clean enucleation."

The eye was sent to the Army Medical Museum, and they reported the preliminary examination on October 9th: "Reveals a retinoblastoma which has extended through the sclera, forming a small orbital tumor mass adjacent to the optic nerve."

In December, 1945, the left eye was enucleated. The child died, January 7, 1946.

OSSIFICATION OF THE CHOROID

DR. E. C. ELLETT reported the case of Mrs. P., who was seen in 1941 with a

history of the loss of the right eye at childbirth, 28 years before. She was said to have had a hemorrhage in or behind the eye. The eye was shrunken and divergent. The pupil was adherent to a cataractous lens. Tension was 18 mm. Hg (Schjötz). She complained of pain around the eye and was advised to have it removed. The pain has continued in the eye and head without any change in the eye, but recently the eye seems tender and the possibility of ossification of the choroid suggested itself. X-ray pictures were taken by Dr. Anthony who will report on them.

GLAUCOMA SIGNS AND SYMPTOMS

DR. E. C. ELLETT reported a series of cases presenting the signs and symptoms of glaucoma without a rise of intraocular pressure.

Case 1. P. R., aged 60 years, was seen in 1943 with failing vision and a diagnosis of glaucoma two months before. Vision in each eye was 6/6 with glasses. He was a diabetic and on a diet. The discs were definitely white and cupped. Tension in both eyes was 18 mm. Hg (Schjötz). He had had different opinions as to the advisability of operation. Fields were shown. Blood pressure was 175/125. Iridencleisis was performed in the left eye in May, 1943, and five days later in the right eye. In November, 1945, vision was still 6/6 in each eye. Tension was 15 and 23 mm. The discs were the same, and fields as shown.

Case 2. C. D., a man aged 68 years, had had blurred vision in the right eye for a year. Vision in this eye was 6/18 with glasses; in the left eye, 6/6 with glasses. The right eye showed a few lens and vitreous opacities. The optic nerve was white and slightly cupped. There was no overhang. Vessels were pushed nasally. In the left eye, the media were clear. The optic nerve was of a better color and less

cupped. Pupils were 4 and 3 mm. and feebly active. Fields were as shown. Tension was 20 mm. in both eyes. This patient was put on a 1-percent solution of pilocarpine. He was seen by Dr. Arnold Knapp who wrote that he did not think the trouble was glaucoma but was of vascular origin: "that type of optic atrophy with a shallow excavation which is probably due to interference in the nutrition of the optic nerve." He found the tension to be normal. In November, 1945, vision was: 6/15 and 6/6. Tension was: O.U., 30 mm. Fields were as shown.

Case 3. Mrs. C., aged 52 years, was seen October, 1945, with failing vision for a year. Vision in the right eye was poorer than in the left. The disc of the right eye seemed to be partially cupped. The left nerve was normal. Tension in both eyes was 23 mm. In December, the findings were the same. She had been told she had glaucoma and was using pilocarpine. The only field defect was a central blur in the right eye. Vision was: O.U., 6/7.5, with glasses.

Case 4. Mrs. T., aged 78 years, was seen October, 1945. She had been told she had cataracts. Vision was 6/7.5 and 6/15, with glasses. Tension was: O.U., 26 mm. Pupils were 5 and 5½ mm. and feebly active. Incipient cataracts were present. The optic nerves, clearly seen, were pale and slightly cupped. Fields were as shown. She was given pilocarpine drops. A month later the condition was unchanged.

This condition of signs and symptoms of glaucoma without a rise of ocular tension has been long recognized and frequently discussed. Fuchs thought that a weak lamina could yield while the nerve fibers were intact, and might yield before a normal intraocular pressure. Schnabel thought that the primary process was a neuritic atrophy forming small spaces which coalesce. The connective tissue pro-

liferates, contracts, and pulls the lamina back. Duke-Elder describes hypertension as "that pressure which the tissues of that particular eye are unable to withstand without damage to structure or function." Mauthner and Magitot think the condition represents a true glaucoma. Redslob reported a case with tension of 15 to 20 mm. not raised by provocative measures nor affected by a bilateral cervical sympathectomy.

Arnold Knapp, in 1932, made a most significant and valuable observation in attributing the trouble to radiographically demonstrable calcareous degeneration in certain arteries at the floor of the cranial cavity.

PERSISTENT EDEMA FOLLOWING NOVOCAINE INJECTION

DR. J. WESLEY MCKINNEY reported the cases of Mrs. L. R. and Dr. C. G. T. On December 11, 1945, a small chalazion of the right lower lid of Mrs. L. R. was curetted after novocaine infiltration. On the following day, December 12, a chalazion of the right upper lid of Dr. C. G. T. was curetted after novocaine infiltration. In both of these patients, there resulted a marked edema of both the upper and lower lids without induration or tenderness. There was no infection about the wounds which healed uneventfully. The edema, however, was of such degree as to be incapacitating for both and persisted for approximately four weeks in the former, and three weeks in the latter. The technique of injection and preparation of the novocaine from the ampules was, as far as we could determine, no different from that usually employed. From the box of novocaine ampules, three injections without unusual reaction had preceded these two. The remaining ampules were sent to the Winthrop Company for analysis. No impurity was found in the ampules examined.

BASAL-CELL CARCINOMA OF ORBIT

DR. J. WESLEY MCKINNEY reported the case of Mrs. J. T. P., aged 68 years, who gave the history of a sore at the inner corner of the right eye for nine years. This sore had gradually spread in spite of three series of five X-ray treatments. For the past three months there had been much pain, and there was an annoying diplopia.

Examination. Vision was: O.D., 6/12; O.S., 6/6. The left eye was normal. Between the right eyeball and medial wall of the orbit, there was a deeply excavated ulcer with granulating sides; the globe was fixed by the mass of infiltrating tissue. The eye was internally normal. General physical examination was negative.

On February 29, 1944, the right eye was enucleated, and the large electrocautery was applied widely to the orbital tissues. The cautery was held against the bone, nasally, to insure that any cancer cells that might have invaded the bone would be killed. Pathologic report was basal-cell carcinoma. The immediate post-operative course was uneventful. Over a period of several months, the orbital tissues granulated and became clean. Sequestra of bone have been removed from time to time. There are now several openings into the ethmoid and maxillary sinuses. No evidence of recurrence has been noted in the nearly two years since operation.

LYMPHOSARCOMA OF THE ORBIT

DR. J. WESLEY MCKINNEY reported the case of G. H. R., a man aged 59 years, who was first seen August 13, 1943. The history was that there had been swelling about the left eye for about three months. Three weeks before, the swelling had become rapidly more marked. Vision was much impaired. There was a feeling of fullness but no pain. He complained of general weakness.

Examination. Vision was: O.D., 6/6;

and O.S., 6/18. The right eye was normal except for a slight puffiness of the lids and a small subconjunctival hemorrhage, temporally. All around the left eyeball and displacing it inward was a firm mass which caused protrusion of the lids. A globular mass was seen pushing out the upper fornix temporally. The globe was fixed by the mass. The pupil was active, and the eye was internally normal.

A biopsy was taken from the subconjunctival mass, and the laboratory reported a highly malignant tumor of probable connective-tissue origin resembling melanoma without pigment and probably not radiosensitive. He was sent to an internist who reported no evidence of tumor elsewhere.

On August 20th, an exenteration of the orbit was performed, including the lids and periorbita. The entire mass was sent to the Army Medical Museum. The report sent back was: lymphosarcoma, mixed reticulum-cell type. On September 3rd, a small mass appeared in the right upper lid which disappeared promptly under X-ray therapy. On September 14th, many subcutaneous nodules appeared over the entire body. Three weeks later the patient died.

PANOPHTHALMITIS FOLLOWING IRIDENCELEISIS

DR. PHILIP MERIWETHER LEWIS reported the case of G. P., a white man aged 73 years, upon whom he had done a bilateral iridencleisis in 1937 for chronic simple glaucoma. For over eight years, the intraocular pressure remained normal and useful vision was maintained. About December 15, 1945, the left eye became quite red and sore. The pain became worse every day and, when seen on December 22, 1945, a purulent panophthalmitis was present. There was a spot of complete necrosis through the conjunctiva at the site of the scleral opening. Evisceration

was performed immediately. A purulent infection involved every structure of the eye except the lens. Penicillin ointment was put in the scleral cavity, and 20,000 units of penicillin were given intramuscularly every three hours for 10 doses. Recovery was uneventful.

This was the only panophthalmitis following iridencleisis seen in about 12 years' experience with that operation for glaucoma. It had occurred in two cases following trephines.

COLLEGE OF PHYSICIANS OF PHILADELPHIA

SECTION ON OPHTHALMOLOGY

December 20, 1945

DR. WARREN S. REESE, *chairman*

AMBLYOPIA DUE TO DIETARY DEFICIENCY

COMDR. A. D. BEAM (MC) U.S.N.R. (by invitation) reported on eight cases.

Early in the spring of 1944, the United States Naval Hospital in Philadelphia was designated by the Surgeon General as the national center for the rehabilitation of blinded personnel of the Navy and Marine Corps. Only those men whose vision was 20/200, or less, in the better eye, with correction, were admitted to this special service. At the time of the report, there had been 165 admissions. Of these patients, 101 had suffered loss of vision as a result of traumatic injury; 29, as a result of methyl-alcohol poisoning; and 27, following various ocular diseases. The remaining eight patients became blinded during their period of imprisonment under the Japanese. It is this prisoner-of-war group of patients with whom we are concerned in this report.

All eight of these men, with normal vision on enlistment, were captured at the fall of Corregidor. Five of them were marines and three were sailors. Only one

of them had sustained physical injury during the encounter prior to capture, and that injury was confined to the lower extremities. All of them were between 20 to 32 years of age. For a period of five months before capitulation, their living conditions had been far from satisfactory, and their diet had been rationed and steadily reduced. Following capture, all eight of these men survived the death march from Bilibid to Cabanatuan where six of them were imprisoned until the date of liberation on February 4, 1945. The remaining two had been taken to Japan after they had begun to have visual deficiency.

During their period of imprisonment, all of them were forced to engage in strenuous physical labor and suffered the physical hardships of a discipline now so well-known to all of us. Weight loss of these eight men varied between 40 to 70 lbs. Diet during the entire period of incarceration was far below that specified by international law. The average daily intake was 200 to 300 gm. of polished rice (about 7 tbs.), and a thin soup, made from sweet-potato vine, was given about three times a week. This constitutes a diet of approximately 1,000 calories per day. Occasionally the intake was greater or less, but this represents the usual food intake. All of these patients showed evidence of severe beriberi, and seven of them had pellagra of varying degrees of intensity.

Visual loss appeared in all of them without other specific prodromes and proceeded to the maximum deficiency in one to four weeks. Blindness in all of these prisoners developed between 4½ to 8 months after capture. Once the loss of sight was established, it remained static, even after they were freed and given various forms of therapy. Loss of vision was painless in each instance and, other than the signs of dietary insufficiency,

there were no common factors that would suggest a toxic, infectious, or traumatic etiology.

Seven of the patients also developed bilateral-nerve deafness; the loss of hearing varied from 11 to 36 decibels. Deafness was a feature concomitant with visual loss and was first noted at the time of blindness or soon thereafter. All of these eight men had some evidence of peripheral neuritis, as did nearly all of the other prisoners. None of these men had symptoms of night blindness but, on the contrary, found that their vision was better during twilight or early evening. Hypoproteinemia and occasional bouts of diarrhea were common to all of the prisoners, including those under discussion. All of these patients stated that there were many other prisoners who developed blindness in a similar manner, but who failed to survive the period of confinement for one reason or another.

These eight men with severely impaired vision present histories and physical findings which indicate that their visual loss probably resulted from dietary deficiency. However, the possible effect of some chemical intoxication cannot be completely disregarded, even though there does not seem to be any common factor. The effect of a prolonged deficiency diet upon the visual sense of man during a period of strenuous and enforced labor has never been determined. Therefore, the etiology may have been influenced by three groups of factors: (1) deficiencies in such required elements as vitamins, minerals, and proteins; (2) intoxications of a chemical and bacterial nature; and, (3) the effect of strenuous physical activity with inadequate caloric intake. We feel that we are unable to state just what influence each of these would have had upon the development of blindness under the circumstances just related but, from the endless array of published data, it

would appear that avitaminosis would be the principal factor to consider. However, in discussing vitamin deficiencies, I do not intend to exclude the possible effects of other contributing factors or to indicate any assessment of their influence.

Only the vitamins usually thought to be concerned with the physiology of the eye will be considered, excluding vitamin D.

Vitamin A. The minimum daily requirements for vitamin A is considered to be about 5,000 international units. The source of vitamin A in the diets of these men was limited to that contained in the thin soup made from vegetable leaves and water. None of these men suffered night blindness and only two showed evidence of corneal disease upon admission to our hospital. One patient had developed a perforating corneal ulcer in his right eye, although there were no opacities nor history of inflammation of the left eye. On examination, the lower two-thirds of the cornea of the right eye was opaque and vascularized, and there was an anterior synechia. The left eye did show proliferation of the limbic vessels. One other patient had suffered "sore eyes" three months after capture. An American doctor told him that he had corneal ulcers, which became symptomless with no change in diet and the treatment limited to instillation of yellow oxide of mercury, once daily. When this man was first examined here, there were seven or eight superficial opacities of each cornea associated with well-marked proliferations of the limbic vessels. The corneal opacities were not dense, and there was very little loss of corneal substance. These two cases may represent keratomalacia and xerosis of the cornea respectively, although neither of them showed evidence of conjunctival xerosis nor had they suffered hemeralopia.

Vitamin B₁. Vitamin B₁, or thiamin, has been proved necessary in maintaining normal neurologic function. Inadequate ingestion, absorption, or utilization of this heat labile portion of the vitamin-B complex causes the disease known as beriberi. The Committee on Nutrition of the National Research Council recommends between 1.5 and 2 mgs. daily for a well-balanced diet.

The rice which these men ate was chiefly polished. The polishing process, like the milling of flour, removes valuable constituents, notably the vitamins, protein, and mineral elements. The discovery that a diet which consists solely of polished rice will produce beriberi gave an early incentive to the study of vitamins. Polished rice is practically devoid of all vitamins, but beriberi is due specifically to the lack of vitamin B₁.

Each man in this group suffered symptoms of severe beriberi including peripheral neuritis, edema of the extremities, weakness, anorexia, and diarrhea. Palpitation and shortness of breath were noticed by three of them. Massive doses of vitamin B₁, given upon liberation in 1945, relieved all of these symptoms, but the amblyopia which had occurred during the attack of beriberi was not improved. One patient received large doses of vitamin-B complex, seven months after his vision failed, when the Japanese picked a group of 100 prisoners, all suffering from beriberi, to half of whom they gave vitamin therapy in addition to the usual diet; the other half of the group was kept on the unfortified rice and soup diet. This man improved during this study as far as his neuritis, edema, and weakness were concerned; however, there was no change in his vision during, or following, the six weeks of the experiment.

On admission to our service, the vision of these eight men ranged from 1/200 to 10/200 in the better eye. Each had bi-

lateral, absolute, central scotoma which extended 5 to 12 degrees from the fixation point; two also had bilateral, concentric contraction of the peripheral fields. The pupils were semidilated and reacted sluggishly to light. Fundusoscopic examination was essentially normal, except that each man showed evidence of bilateral optic atrophy varying from well-marked temporal pallor to advanced optic atrophy. The atrophy was of the primary, or descending, type. Treatment consisting of high vitamin diet supported by large doses of thiamin has failed to cause any visual improvement in these cases. There has been considerable evidence in the literature to support the theory that lack of thiamin in the diet may cause retrobulbar neuritis and optic atrophy, if the condition remains untreated. The dietary deficiency in chronic alcoholism is a classic example.

Vitamin B₂. Pellagra is a disease of nutrition caused by deficiency of vitamin B₂, or nicotinic acid. Although other factors of the B complex may contribute to this disease, their significance is uncertain. Typical cases of pellagra are characterized by three groups of symptoms: (1) a typical form of dermatitis; (2) digestive disorders with or without diarrhea; and (3) psychoses of the confusional type. Typical signs of this disease occurred in seven of the eight cases presented. The other patient apparently had no evidence of pellagra even to the extent of glossitis, which is often one of the first signs of nicotinic-acid deficiency. Although peripheral neuritis and optic atrophy have been attributed to this disease (P. B. Wilkinson), it is probable that concomitant vitamin-B₁ deficiency is the true etiologic factor. Optic atrophy and peripheral neuritis occurring in the one patient who suffered no signs or symptoms of pellagra tends to support this belief. These men suffered no ocular

change which we feel can be directly attributable to nicotinic-acid deficiency. Their pellagra healed soon after liberation, when they received large doses of vitamin-B complex.

Riboflavin. In 1940 Sydenstricker described the ocular effects of a riboflavin deficiency which included the symptoms of photophobia, sensations of roughness or burning of the eyelids, and visual fatigue. The commonest sign was circumcorneal injection, often with invasion of the cornea by capillaries from the limbic plexus. Superficial corneal nebulas were also noted. These signs and symptoms responded favorably to riboflavin therapy. Four men in this group had a history of "sore eyes" and photophobia during their period of incarceration. Three of the four exhibited definite limbic proliferation, and one showed superficial corneal opacities upon examination here. The remaining men showed no evidence of limbic proliferation. Local areas of proliferation, usually traceable to some antecedent corneal inflammation, were not considered. Symptoms of photophobia and burning were relieved soon after liberation, when adequate vitamin therapy was instigated; however, no change in the vessel proliferation was noticed during the past 8 to 10 weeks. Riboflavin (5 mg.) has been administered daily since they arrived here.

Vitamin C. The eye manifestations of vitamin-C deficiency are probably limited to ocular hemorrhage in patients with scurvy. However, there is some evidence that cataract formation may be influenced by lack of this vitamin in the diet. Three of these cases were told that they had scurvy at one time or another while prisoners on Luzon. Their description of the skin lesions is not typical, although their gums were swollen and bled easily. They gave no history of subcutaneous hemorrhage nor bleeding other than from the

gums and nose. Examination here revealed no ocular pathology attributable to vitamin-C deficiency.

Comment. In this group of eight men who became amblyopic on an inadequate diet during imprisonment, the outstanding ocular pathologic change common to all eight of them was the optic atrophy with central scotoma in each eye. Dietary deficiency, notably vitamin-B₁ deficiency, appears to have been the etiologic factor. Signs and symptoms of severe beriberi were present in each case; thus establishing proof of thiamin deficiency. An analysis of the diet, the bulk of which was polished rice, reveals little or no source of this vitamin. Rice, containing 79.4-percent carbohydrates, 7.6-percent proteins, and 0.3-percent fat, gave these men a high carbohydrate diet. It has been well established that thiamin requirements increase with the carbohydrate intake and with physical exertion. Ten hours of hard labor per day, associated with a high carbohydrate diet increased the vitamin-B₁ requirements. The need for thiamin was great, and the source was negligible. There is lack of evidence to support the influence of other avitaminosis on the amblyopia which these patients suffer.

Again, no attempt has been made to evaluate the significance of other possible contributing factors—dietary deficiency, intoxication, or circumstances of existence such as these men endured. Only under highly controlled circumstances could such a study be of definite value. Certainly these variable factors cannot be assessed in retrospect.

Discussion. Dr. Walter I. Lillie said that Dr. Beam, in presenting this series of cases and in describing typical, chronic retrobulbar neuritis with resulting simple optic atrophy due to vitamin-B deficiency, in sailors and marines who were prisoners of the Japanese, had definitely shown that they were actually due to the deficiency of vitamin B₁. Similar cases in the

Army personnel had been seen by him at Valley Forge Military Hospital; so one could conclude that all branches of the service, under similar conditions, were similarly affected. One of the sailors noticed that, on the polished-rice diet, his vision diminished; but, when he was fed the unpolished rice, his vision would improve. He always made an effort to obtain as much unpolished rice as possible. Dr. Lillie warned that in treating debilitated conditions due to dietary insufficiency, one must be careful in using glucose intravenously. If it is not fortified with vitamin B, it will utilize the remaining vitamin B in the body tissues and produce an added deleterious effect.

Dr. Lillie complimented Dr. Beam on the excellency of his presentation.

A METHOD OF CLOSING THE CATARACT INCISION

DR. P. H. DECKER (by invitation) described a method of closing the cataract incision by sliding a large conjunctival flap from above down over a corneal scleral suture. He said that this conjunctival flap will temporarily bury the corneal-scleral suture and the entire line of limbus incision. About the fourth or fifth day, the conjunctival sutures spontaneously cut out, allowing the conjunctival flap to retract; thus automatically exposing the corneal-scleral suture which is removed about the 10th day.

The principles behind this procedure are: (1) the corneal-scleral suture gives adequate strength to the incision closure preventing vitreous loss; (2) the conjunctival flap gives an adequate sealing effect to the incision closure, allowing rapid and early reformation of the anterior chamber. Combining these two principles—the corneal-scleral suture and the large sliding conjunctival flap—gives two elements needed in cataract incision closure; namely, guarding against vitreous loss and against slow reformation in

the anterior chamber with its accompanying complications. A film showing the above operative procedure in six cases was presented.

Discussion. Dr. William Zentmayer said that, in looking up the literature for Dr. Decker, he had found that this procedure had been employed in cataract operations by Kuhnt.

Kuhnt makes a large conjunctival flap, as described by Dr. Decker, and, in addition, makes a horizontal incision well up in the cul-de-sac, which allows greater freedom in bringing down the flap and, therefore, better coverage of the wound than can be obtained without that incision.

Dr. Edmund B. Spaeth said that he had had the pleasure of seeing Dr. Decker's film with him at his home so that Dr. Decker knew, at least in part, what he was about to say for they had had a discussion at that time. It seemed to Dr. Spaeth that too much stress had been laid upon necessity for firm closure. Dr. Decker's two lateral sutures with the sliding conjunctival flap will give this under all but extraordinary circumstances. At the same time, the conjunctival flap should seal off the anterior chamber. Dr. Spaeth agreed with Dr. Decker as to the necessity for closing the anterior chamber promptly. For years he had used the conjunctival flap closure on all cataract operations in one-eyed individuals. Nonformation of the anterior chamber, if it continues for more than two or three days, can cause serious consequences. Dr. Decker's beautiful film presents that, without any possible difference of opinion, in a most conclusive manner.

Dr. James S. Shipman said that he, also, would like to congratulate Dr. Decker on this beautiful presentation of a very interesting subject. From the pictures that had been shown he could not see the necessity for using any suture. The way those cataracts were delivered and the

way Dr. Decker had his patient's eyes stay so still was beautiful to see. Dr. Shipman asked what kind of anesthesia had been used. In every cataract, that was shown, the operation was done very skillfully and with very little trauma. Certainly, so far as could be seen from the picture, there was no danger of immediate loss of vitreous.

The only excuse for a suture in these cases would be for the second reason—that of delayed closure of the anterior chamber. In Dr. Decker's technique, as nice as it was, Dr. Shipman did not once see where he replaced the iris pillars. What happens to these? Were the pupils dilated with atropine or homatropine? What drug was instilled at the first dressing? Was it atropine or not? These, are important points that have a great deal to do with the closure of the anterior chamber and, if the pillars are not replaced, they are going to be incarcerated to a certain degree and lead to a slow closure of the anterior chamber. Dr. Shipman said that he believed that there was no necessity for using atropine for the first dressing when there has been a good intracapsular extraction, as in all of these cases. Atropine is necessary in an extracapsular extraction where there is a lot of cortex, but, when a complete intracapsular extraction has been performed, there is no necessity for it. Certainly, there is no necessity for atropine until the anterior chamber has reformed and, in Dr. Shipman's experience, the major portion of them do reform within 24 to 48 hours after operation. He thought that a large conjunctival flap was a great help in getting the anterior chamber to reform and eliminated one of Dr. Decker's objections to cataract extraction without a suture; namely, the second objection—slow closure of the anterior chamber.

Dr. Shipman said that he had not come to believe that sutures were necessary for safe cataract surgery. He said that he

could do a better operation without them, and that he did not use them except on very rare occasions. He used one the preceding week in an eye that he knew had vitreous in the wound which was the result of a basal iridectomy. The man was a very poor patient, and his facial nerve was not blocked. Later, the lens had to be removed. Dr. Shipman felt that vitreous would present itself when he made the section. The iridectomy incision was enlarged slightly; then, three corneal-scleral sutures were inserted before the section was completed. In spite of this, vitreous was still seeping from the wound 10 days after extraction. Dr. Shipman said that he could not be convinced that corneal-scleral sutures or conjunctival sutures, as described by Dr. Spaeth in his discussion, would keep the vitreous in when it was going to come out. If vitreous is going to be lost, it will be, regardless of any suture. He still felt that a well-made corneal section, with a good conjunctival flap, was the best operation for cataract extraction.

Dr. P. H. Decker (closing) said that he wished to thank Dr. Shipman for his remarks, but he still felt sutures were necessary, at least in his hands. In regard to replacing the iris pillars, this was always done when there was any question of incarceration. He did not show this step in order to conserve film; however, he might add that he did not always insert an instrument into the anterior chamber after the extraction in order to replace an imaginary incarceration, as he felt that there was danger of inadvertently rupturing the hyaloid membrane by doing any unnecessary intraocular instrumentation after the extraction of the lens.

George F. J. Kelly,
Secretary.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

January 7, 1946

DR. MAURICE L. WIESELTHIER, *presiding*

WAR SURGERY IN OPHTHALMOLOGY

DR. SIDNEY FOX said the title of his paper was correct only in so far as it applied to the eye center to which he was assigned. This was one of the nine eye centers set up when it became apparent, after the Normandy invasion, that the 65 general hospitals could not handle the large number of casualties. At the peak of activity 75 to 80 percent of the admissions were surgical cases. Later, about 50 percent were medical eye cases, half being nonspecific iridocyclitis; the others included optic atrophy, keratitis, and other metabolic disturbances in released prisoners of the Japanese. The first 500 operations performed in 1944 were divided as follows:

Defects (plastic repair)	235	47.0%
Secondary orbital implants	60	12.0%
Enucleations	47	9.4%
Cataracts	44	8.8%
Intraocular foreign bodies	27	5.4%
Muscles	25	5.0%
Glaucoma	15	3.0%
Retinal detachment	13	2.6%
Lacrimal operations	7	1.4%
Miscellaneous	27	5.4%

Operations after these 500 showed a greater proportion of plastic and lacrimal-sac operations. As a time-saving procedure for orbital implants, the use of purse-string sutures was abandoned, and two crossed-mattress, chromic sutures for Tenon's capsule with a running conjunctival silk suture were substituted with satisfactory results.

There were some senile cataracts, but most cataracts were traumatic and were usually removed by linear extraction. A

spatula, bent like a hook, was devised to slip under the iris to separate synechiae in the 11- to the 1-o'clock positions to eliminate the need for iridectomy in these cases.

Most intraocular foreign bodies were removed overseas. In the few cases which were seen, it was found that the giant magnet had little advantage over the hand magnet. The prognosis in these cases should be guarded, as in some eyes from which foreign bodies were successfully extracted with subsequent clearing, there occurred a late degeneration. A pars-plana approach was favored. In some of the cases, air was injected after the extraction but, in many of these cases, fibrous tissue resulted in multiple air pockets.

The traumatic-muscle cases were not operated upon until a year after the injury. Many of the squint operations were for strabismus present before entering the army. Many of the glaucoma cases were not the result of war trauma. Surface cyclodiathermy proved a satisfactory operative procedure. Ten of the 13 retinal-detachment operations listed were nontraumatic. A combined surface and penetrating diathermy operation was performed. Many of the patients had great damage to their lacrimal sacs, nasal, ethmoid, and lacrimal bones, and the number of these cases increased later in 1944 and in 1945. Lipiodol was injected to show the extent of the trauma. A large number of dacryocystorhinostomies were performed.

Possibly the most characteristic type of case resulted from burns after gasoline explosions in airplanes and tanks. Plastic repairs were required in these cases for loss of skin, shortening and loss of the eyelids, ectropion, and so forth. Powder burns were also common, and powder particles were found in tremendous numbers in the skin and eye.

To remove deeply embedded corneal foreign bodies a V-shaped incision was made in the cornea—the apex toward the center, the foreign body lying between the two arms—and a beveled flap was cut down from the apex. When the foreign body was approached, the flap was reflected, the foreign body removed, and the flap patted back in place. Only once was the cornea penetrated with loss of aqueous but with no adverse result.

Slides were presented illustrating the various types of cases.

VISUAL PROBLEMS IN AVIATION

MAJOR ERNEST A. PINSON (MC) said that associated with the operation of the Army Air Forces was the necessity for development of equipment which will measure or enhance certain visual functions used in flying. In certain instances, considerable research went into the development of such equipment to insure that it would serve the desired purpose when development was complete. Some of the equipment developed in the A.A.F. during the war years to solve certain problems relating to vision were: (1) The A.A.F.-Eastman Night Vision Tester for rapid testing and classification of large groups of flying personnel with respect to night vision. (2) The Radium-Plaque Night-Vision Tester, a small compact instrument which could be carried in a flight surgeon's kit, for testing at the squadron or group level. (3) Red goggles for wear in lighted ready rooms to keep the eyes of personnel dark adapted so that immediate efficient use of the eyes could be made outdoors at night; for example, in case of a hurried take off on an interceptor mission. (4) Anoxia demonstration charts to show flying personnel the reduction in visual efficiency at night due to anoxia, even at low altitudes, in case supplemental oxygen is not used on night flights. (5) Colored plastics for use

in blind flying training. This includes a combination of yellow or amber plastic over the windscreen plus blue-lensed goggles worn even in sunlight; whereas, the instructor who wears no blue goggles can see clearly through the yellow windscreen. (6) Special lenses for goggles and sun glasses. Amber lenses are used for haze penetration; graded-density lenses for scanning directly into the sun; rose-smoke lenses for glare protection and haze penetration.

Discussion. Dr. Howard Agatston said that Major Pinson's ingenious test for dark adaptation measures the degree and not the rate of adaptation. The time factor is not taken into consideration, and there is not always a high correlation between the degree and rate of dark adaptation.

Night blindness is a military medical problem from several standpoints. Shortly after the liberation of American soldiers from Nazi prison camps in April, 1945, it was noted that a large proportion of the men had nocturia and were unable to find their way to the latrines. Not having access to a biophotometer, 82 liberated soldiers were tested by exposing them to an X-ray viewing box for 10 minutes, then measuring the time it took for them to recover fully a 30-degree field either on a tangent screen or on a campimeter, in a dimly lit room. About 50 percent of this group, examined approximately one month after liberation, had prolonged adaptation times. Several malingerers showed normal rates of dark adaptation with concentric constriction of the field to 10 or 15 degrees, and there was little or no increase in the field taken in ordinary daylight. Perhaps the field of usefulness of Major Pinson's test could be widened by the addition of a time element and by its further adaptation for use in the diagnosis of malingering.

Major Pinson said that in a night-vision test, interest was in measuring the

ability of the man to see under conditions which prevail at night. A good test must be correlated with this function. There is only a fair correlation between the rate of speed of dark adaptation and the terminal-rod threshold. The correlation between terminal-rod threshold and ability to see at night is very poor.

A satisfactory test for catching malingerers on dark-adaptation or night-vision tests has been developed. It depends on optokinetic nystagmus over which the examinee has no voluntary control. It has not been designed for field use but could be set up in a laboratory or hospital somewhat behind the front lines.

EXPERIENCES IN THE PRACTICE OF OPHTHALMOLOGY IN THE ARMY

DR. FREDERICK H. THEODORE said that in military ophthalmology routine classification work is of great importance. The military ophthalmologist tends to forget that different persons with the same refractive error may see differently without glasses, especially myopes. Furthermore, there is an unfortunate tendency, particularly among less experienced examiners under pressure, to call a soldier a malingerer without obtaining positive proof by means of malingering tests, just because no cause for the impairment of vision can be discovered. In this connection, the frequency of amblyopia of unknown origin should be emphasized. In a survey of 190,012 soldiers undertaken by the author and his coworkers, 10,532 were found to have impaired vision in at least one eye. In 23.82 percent or 2,509 of these men, poor vision had to be classified as of unexplained amblyopia.

Certain eye conditions that appear of minor significance in civilian life assume much greater importance in the Army, especially under field conditions. Outstanding among these conditions is night blindness. Cases of minor-degree night blindness, without obvious retinal find-

ings, are often disregarded. As a result, there may be malassignment of the individual soldier with serious consequence. Vernal catarrh is another condition which can become intolerable in warm climates. It is generally overlooked on induction. Hay fever falls in the same category. Men become sensitive to allergens that never bothered them clinically before.

Some eye conditions seem to be encountered more frequently in the Army than in civilian practice. These include primary, meningococcic conjunctivitis, nine cases of which Dr. Theodore had seen, and exudative choroiditis, which occurred in the younger soldiers. The importance of routine bacteriologic studies in acute conjunctivitis in the Army must be stressed. In heat stroke, retinal hemorrhages were seen in two cases. The local use of penicillin has resulted in so many allergies that its indiscriminate use is to be avoided.

In analyzing unpublished data concerning 41,000 men examined for aviation-cadet training, the inadequacy of the Howard-Dolman depth perception test was obvious. The value of routine screen and cover tests and testing of ocular motility was indicated by the uncovering of many cases of tropisms, otherwise overlooked and not picked up by routine photometer measurements.

REVIEW OF CONTRIBUTIONS OF WORLD WAR II TO OPHTHALMOLOGY

DR. RICHARD J. HESSBERG pointed out that modern ammunition with its high explosive force produces extensive damage to eyes, orbit, face, skull, and brain; therefore eye injuries are often combined with head injuries.

All ophthalmologists recommend sending eye injuries to eye departments at rear hospitals as soon as possible. At the first-aid station, only cleaning and dressing should be done. Most of the eye injuries resulted from mine explosions.

They produced perforating wounds with or without intraocular foreign bodies. Direct suture of corneal wounds is the method of choice. Only gaping perforations need conjunctival flaps. For the extraction of the foreign body a delay of 48 hours seemed to be less dangerous than lack of skilled care. Successful extraction is based on accurate localization with X ray. The multitude of foreign bodies and the overwhelming majority of small nonmagnetic ones made the posterior route the method of choice for the extraction of magnetic and nonmagnetic fragments. Severely damaged eyes should be enucleated with the least possible delay. Only in cases of purulent endophthalmitis is evisceration more advisable.

Blast effects are a new type of war injury due to detonation of high explosive bombs. The blast waves cause serious damage to the interior of the eye, rupture of the sclera, even complete loss of the globe.

Orbit and face were often injured, together with the eyes, by mine explosions. Important complications are injuries of nose and sinuses which menace the eyes and opening of the skull and which may be dangerous to life. Complete exenteration of the orbit and careful examination of nose and sinuses are necessary to protect the dura mater, if cerebro-spinal fluid is secreted from orbit or nose. An early spectacle-shaped hematoma of the lids is caused by multiple fractures of the orbit.

Severe burns of face and eyelids were produced by high explosive and incendiary bombs and by burning gasoline. The extensive defects of face, socket, and eyelids require skillful plastic reconstruction. The ophthalmologist doing reconstruction work has to choose the simplest procedure within the shortest time for the best restoration of form and function.

Discussion. Dr. Morris Davidson said that the New York Society for Clinical Ophthalmology ought to be congratulated

for starting this initial survey in the lessons of the war for the ophthalmologist and for the community. This was only the first installment of the survey of ophthalmic literature. The term "contributions," implying a constructive purpose, he felt should be discarded. Wars do not make any contributions to society. They only teach lessons.

Leon H. Ehrlich,
Secretary.

SOCIEDAD OFTALMOLOGICA DE MADRID

January 25, 1946

SUBRETINAL CYSTICERCUS

DR. MARIO ESTEBAN described a case of subretinal cysticercus (with presentation of patient). In this case, the first manifestation was an iridocyclitis. In the course of this condition it became possible to make out the presence of a subretinal cysticercus in the form of a smooth and transparent vesicle located in the infero-external sector.

The clinical aspect of the cysticercus was described, with discussion of the differential diagnosis of retinal detachment, choroidal tumor, and so on. As to treatment, surgical extraction must be attempted as early as possible, before the mechanical action of the presence of the cyst and the toxicoanaphylactic action of the parasite lead to greater changes in the eye, and before the cysticercus migrates into the vitreous, where its seizure would be more difficult and dangerous.

Discussion. Dr. G. Díaz García del Viso congratulated Dr. Esteban on his study, and referred to a case treated primarily with five or six sessions of radiotherapy without any change on the part either of

the parasite or of the eye. The speaker had read later that radiotherapy had no action on cysticercus. Upon a suggestion by Dr. Basterra Santacruz, the cysticercus was killed by electrocoagulation, but after eight or ten days there began an iridocyclitis with hypopyon and marked pain, which made enucleation necessary.

The speaker agreed that the best treatment was surgical intervention with extraction of the parasite, in view of the certainty that even though diathermy killed the parasite it was sure to be followed by allergic reaction or by toxic action of the products of disintegration of the dead parasite.

CYSTIC FORMATION IN A PTERYGIUM

DR. MARIN AMAT showed a clinical case of cystic formation in a pterygium, and another case of melanotic tumor of the iris. He would later make these cases the basis of other communications.

FOREIGN BODIES OF THE ORBIT

DRS. M. MARIN AMAT and M. MARIN ENCISO stressed the importance of exact localization and interpretation of foreign bodies of the orbit (with projections). A patient with an extraocular foreign body of the orbit (from birdshot, while hunting), showed displacement of the radiographic shadow during movement of the eye, ecchymosis of the bulbar conjunctiva exactly corresponding with the wound of palpebral penetration, and hemorrhage into the vitreous. The authors called attention to the importance of differential diagnosis between intraocular and extraocular foreign bodies by means of good radiographic technique and perfect physiologic interpretation.

The symptoms were modified by the fact that the shot had glanced off of a stone, diminishing the force of penetration, and the shot remained incarcerated in the fibrous tissue of the adherent bor-

der of the upper lid, producing merely contusion of the eyeball and secondary hemorrhage. The patient had been looking down at the time of the injury. In the normal position of the open eye the foreign body would have lodged inside the orbit and would have escaped digital exploration. In lateral radiography in two exposures (looking up and looking down), the upper lid would follow the movements of the eyeball and thus produce a double shadow on the radiographic plate, instead of a single shadow. This, and a radiographic technique with the contact glass, would establish the true differential diagnosis.

Discussion. Dr. Gregorio Diaz Garcia del Viso said that, of the different methods of localization of intraocular foreign bodies, there are few which determine whether the foreign body is or is not intraocular so distinctly and conclusively as in the case presented by Drs. Marin Amat and Marin Enciso. Either of the methods described (contact glass, Casanova's ring, or that of Vater) are good and usually avoid uncertainty; but in other cases a distinction between extraocular and intraocular is difficult.

Closing, Dr. Marin Amat said that Comberg's contact-glass method was excellent, since the so-called geometric procedures, beside being complicated, required especial apparatus not always available. Injection of air into Tenon's capsule may mask the presence of the foreign body and is not always free from danger.

are, however, lesions of the canaliculi in which this operation cannot be performed for the very nature of the inflammation of the sac (tuberculosis and so on) contraindicates it. On the other hand, cases are encountered in which, in spite of the most perfect technique, the operation fails. In all such cases, having once eliminated lacrimal suppuration, the operation indicated is that of removing the lacrimal gland. The speaker has abandoned extirpation of the gland on account of the dry conjunctivitis which it produces. More recently he has used injections of alcohol, which, however, are inconstant in their action and have rather disagreeable consequences. Diathermocoagulation of the palpebral gland and of the excretory passages of the orbital portion is a harmless and often very successful operation. To avoid later dry keratoconjunctivitis, it is necessary to exclude those cases in which there exist conjunctival alterations of such a nature as to suggest failure of function of the accessory lacrimal glands, as found, for example, in trachoma. Also to be kept in mind are Sjögren's syndrome (menopause, dryness of the mucosas, rheumatic troubles, and so on). Discussion by Drs. Marin Amat and Esteban.

SOCIEDAD OFTALMOLOGICA DE MADRID

SCIENTIFIC SESSION

February 22, 1946

CONSIDERATIONS CONCERNING LACRIMATION

DR. GARCÍA MIRANDA reviewed the various forms of therapy used for dealing with epiphora. He then insisted on the usefulness of dacryocystorhinostomy, which he considered the operation of choice in cases of dacryocystitis. There

NEVUS FLAMMEUS AND GLAUCOMA

DR. CASERO (from the Clinic of Prof. García Miranda) said that it is interesting that localization of nevus follows the distribution of the branches of the sensory nerves, that is of the nerves of vegetative life. There are two types: (1) The type in which the nevus is accompanied

by late appearance of a simple glaucoma; (2) the type in which the nevus, from birth, accompanies hydrophthalmos. As regards the cases with glaucoma, these are now regarded as due to telangiectasis in the ocular fundus, especially the choroid; although existence of a nervous factor cannot be excluded. The radiologic appearance of this condition was described by Weber in 1923, including the appearance of parallel curved lines of calcification corresponding to images of the cerebral convolutions, with deposits of lime in the boundary between the gray matter and the white matter. The speaker described a case of nevus flammeus of the first branch of the trigeminus of the left side, with ocular hypertension of 60 mm. Hg reduced to 45 mm. under pilocarpine. The disc was atrophic but did not show glaucomatous excavation. The peripheral field was normal but there was an absolute central scotoma. There were changes in the pyramidal tracts of the brain and also a slight mental debility. There were dilatations of the vessels of the diploe, without Weber's calcifications.

The discussion was led by Drs. Mario Esteban, Marin Amat, and García Miranda.

CONGENITAL ECTROPION OF THE UVEA

DR. BARAHONA (from the Clinic of Prof. García Miranda) described such a case in a girl, aged eight years. The ectropion covered a large part of the iris stroma. As seen under the slitlamp, the iris was perfectly formed, reacted normally to light and convergence, and the eye showed otherwise no anatomic or functional anomaly.

Discussion. Dr. Mario Estaban called attention to differential diagnosis from heterochromia or pigmented nevus of the iris.

OCULAR LESIONS FROM VOLATILE SOLVENTS

DR. GARCÍA MIRANDA described the danger to the eye in occupations apparently harmless, with especial emphasis on ocular lesions from volatile solvents. These substances have metallic action, are irritating to skin and mucosa, and have specific action on the liver, the kidney, the heart, the blood, and the nervous system. In the course of industrial development, such substances are used to a remarkable degree in the making of lacquer for furniture, leather, shoes, artificial silks and gems, in the cleaning of various articles of wear, and in various parasitocides.

In cases of retrobulbar neuritis, the cause of which cannot be determined, it is to be remembered that central scotoma with a variable ophthalmoscopic picture may be the only clinical expression of poisoning by one of these preparations. The speaker's comments were based upon a case in which the left eye showed a post-neuritic optic atrophy and the right eye a simple atrophy with a final picture of retrobulbar neuritis. The patient had worked for 23 years with one such product known as "rudol Michelin." Most persistent clinical investigation did not show any other etiology than presumed intoxication by such a substance. Discussion by Dr. Mario Estaban, with special regard to industrial compensation.

Dr. William H. Crisp,
Translator.

Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, F. C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 55 East Washington Street, Chicago 2, Illinois*; Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin*. Manuscripts should be *original copies*, typed in *double space*, with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 E. Wisconsin Avenue, Milwaukee 2, Wisconsin*.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio*. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THE HEED OPHTHALMIC FOUNDATION

A generously endowed trust fund has recently been established by Mr. and Mrs. Thomas Heed of Chicago. Its purpose is to provide fellowships to qualified individuals who have completed their residencies in Ophthalmology, in order that they may continue their advanced studies primarily in ophthalmic surgery. The conditions are liberal and there are very few restrictions. The successful applicant, or

applicants, will be chosen by a board of directors composed of five ophthalmologists. He will hold the fellowship for a year, or longer if the board is so inclined. The fellowship is limited to American citizens for training in the United States of America. One or more fellowships, depending on the applicants and the availability of places suitable for such advanced training, will be granted each year, at the discretion of the board. The secretary is Dr. M. Hayward Post of Saint Louis.

The creators of the fellowship have rendered a great service to ophthalmology and to the people. The training of an expert ophthalmologist is one of great responsibility and importance. It requires time, experience, and material. Many ophthalmologists are doing eye surgery, but there are relatively few who are outstanding in this meticulous field. There is far too much surgery of mediocre quality being done. This is, for the most part, the result of poor training and lack of opportunity. Many a promising ophthalmic surgeon has had to go into practice at the end of his residency, by force of necessity. He has had to achieve skill and proficiency the hard way, sometimes at a cost to his patients.

A year of further, advanced training under the watchful and paternal eye of a master, or number of masters, cannot help but be beneficial to the public and to ophthalmology. The time spent in the working out of particular surgical problems, research in techniques, observation, the assisting at and the performing of various operations under the direction of a preceptor cannot but be fruitful. To work, free of economic worry and pressure, with men who are outstanding in this field is an opportunity that is superb and without price.

There is a danger that this training might interfere with that of the resident and stifle his chances. This need not be so if the matter is carefully thought out and planned. Much depends on the preceptor and the inspiration that he gives to the Fellow, as well as to the opportunities that are at hand. The members of the board of directors who are experienced surgeons and teachers can be trusted to work out this problem satisfactorily to all concerned. In fact, the resident should benefit considerably by association with the Fellow; each could be of assistance to the other in the surgical workshop.

It may be said, too, that there is a scarcity of clinical material upon which to work and learn. This may be true in most places in so far as the numbers of patients are concerned, but teachers of ophthalmic surgery agree that it is quality and not quantity of workmanship that counts. If talented, one can become a safe, and perhaps excellent, cataract surgeon after the performance of 25 or so cataract operations done the right way. It also holds true that 100 operations done with little or no supervision, especially by a bungler, will leave the cataract surgeon no further along, except for a trail of more or less mutilated eyes behind him. The brutal German saying that "one can only become a surgeon after spoiling a hatful of eyes" is a false one.

Like other fields of endeavor where skill, training, artistry, and "the touch" count, ophthalmic surgery requires much of the man who would excel. He not only must be peculiarly endowed by nature with talent; he must also be inspired by example. He must have a good eye and a steady hand. He must be bold, yet tender. He must have the courage of a tiger and the touch of a butterfly. Above all he must have judgment.

He must develop versatility. There are many violinists but only one Heifetz. There are many fiddlers who can play nearly every piece of music fairly well in the first three positions, but none of these become violinists without further study, training, and practice. Exceptionally few develop the versatility required of a master of the art. There are many ophthalmologists who can do a good cataract operation provided everything goes well, but the possessor of versatility in cataract surgery has saved many an eye that, in lesser hands, would have ended in disaster. It is the function of a good teacher to teach and develop this art in the pupil. It is this type of training in the post-

residential stage that should be emphasized.

There are a number of foundations designed to take care of the patient after he becomes blind, even as the result of poor surgery. The Heed Ophthalmic Foundation is the first, however, planned against a specific source of blindness. In fact, it can be called a "Foundation to Prevent Surgical Blindness." For their generosity in providing the means to elevate the standards of surgical training and to further the development of surgical skills, the Heeds deserve the gratitude of all ophthalmologists.

Derrick Vail.

INSTRUCTION IN OPHTHALMOLOGY BY OPHTHALMOLOGISTS TO NONMEDICAL GROUPS

There has long been a difference of opinion as to whether or not the ophthalmologist would serve the public better by giving instruction to those who specialize in care of the eyes but who have not had the medical training that would qualify them to practice medicine.

The arguments pro and con are for the most part too obvious to need more than mention. On the "pro" side it is almost universally agreed that there will be a continuing use for the refractionist who has not qualified for the practice of medicine or surgery. For everyone who plans to perform refraction to have surgical training is absurd. Three fourths would have wasted their time because there is not now, and never will be, enough surgery for them all to become or remain qualified. Nevertheless, everyone who performs refraction should have a good medical background. Whether this is obtained by improving this part of the teaching in the independent schools of optometry or by associating them with medi-

cal schools, as is now the tendency, is another subject for discussion.

On the "con" side are such arguments as that these nonmedical refractionists will never have sufficient insight into the medical factors involved in refraction and that a full medical and surgical training such as is required by accredited medical schools is essential for intelligent ocular examination. The point is made that, with insufficient medical training, these refractionists invade further and further the medical field and that lectures and instruction by ophthalmologists can never be adequate. Furthermore, those on the "con" side contend that lecturing in optometric colleges gives recognition to non-medical refractionists that ophthalmologists should not encourage.

The heated and prolonged controversy over the optometric resolutions of the Section on Ophthalmology of the American Medical Association testifies to the difference of opinion on the entire subject. Realizing that this is so and recalling the previous difficulties about the resolutions earlier passed by the Section, the "Pros," in order to liberalize ophthalmooptometric relations to some degree, introduced the following resolution at the Section meeting in San Francisco in July: "Whereas, It is not contrary to the Principles of Medical Ethics as determined by the American Medical Association for members of the Association to disseminate information pertaining to matters of public health, such as cancer, diabetes, and venereal disease, by lectures, demonstrations, radio talks, pamphlets and conferences or other means to non-medical groups; and Whereas, Ophthalmic subjects, such as vascular disease, glaucoma, retinal disorders and optic nerve disease, considered as potential causes of blindness are matters of grave importance to the public; and Whereas, The prevention of blindness is one of the chief obligations of

ophthalmologists; therefore, be it Resolved, That the Section on Ophthalmology of the American Medical Association declares that it is entirely within the definition of medical ethics for its members to engage in lectures, demonstrations, the preparation of pamphlets and other measures suitable for the dissemination of information designed to prevent blindness and directed to any non-medical group."

This was passed unanimously and should be adopted when presented to the House of Delegates at its next session. What are the implications of this action of the Section in recognizing the value of permitting the ophthalmologist to give lectures to optometrists? Fundamentally, the resolution recognized the optometrist as a part of the visual program and that, as such, the better informed he is, the better it will be for the public. This goes even further and carries a deeper implication than this and one with which ophthalmologists may not agree. This is the recognition of optometry as a useful and honorable specialty. Why plan otherwise to help its members?

To fail to recognize optometry as an entity is sheer wishful thinking on the part of some ophthalmologists. The hostile attitude between the two groups is detrimental to each and above all to the public that is confused by the repercussions of the conflict. An understanding between the two is long overdue and this would probably have taken place years ago had ophthalmologists been permitted by medical ethics to confer freely with optometrists.

The aforementioned resolution when passed by the Trustees will go a little way toward breaking down the barriers, and free discussions, when possible, may help to delimit the fields of activities of oculists and optometrists. The resolution does not go far enough, but may do something to encourage better relationships.

Most optometrists want to refer as few patients as possible to eye doctors because eye physicians seldom refer patients to them and are sometimes remiss in sending the referred patients back to the optometrist. For this and other reasons, many optometrists wish themselves to conduct, whenever possible, the ophthalmic care of the patient and to consult directly with the internist; for example, in cases of diabetes, retinitis, and brain tumors. Optometrists hope to perfect themselves in diagnosis and many want to give orthoptic training. Most ophthalmologists believe that the optometrists' lack of a broad medical education prevents their having sufficient background to render them competent in the making of diagnoses. The difficulty of doing so is recognized by optometrists, and their leaders are constantly attempting to raise optometric educational standards. It is not inconceivable that their own demands will force such educational requirements in their group and that two or more years of medical training will be insisted on by them for optometric degrees. It may not be, and probably should not be, the same as that required of those who plan to practice in the medical or surgical fields of ophthalmology, but might well be broad enough to enable those who graduate from such schools to perform satisfactorily such functions as most optometrists wish to perform. In that case, the number of oculists may diminish, but this in itself may not hurt the public weal if the work is well done by others.

In brief, many optometrists desire to perform refractions, make fundus examinations, test visual fields, give orthoptic training, fit contact lenses, serve as consultants for medical practitioners, and to attain medical recognition of the title "Doctor." Some would eliminate ophthalmologists from all of the visual fields except the surgery and medical treatment.

The extreme ophthalmic point of view would be the elimination of optometrists from all fields and, on the other hand, no ophthalmologist would accept all of the suggestions of the most radical optometrists. Put in that light, the differences might seem insurmountable, but fortunately in our democratic state there is a certain amount of give and take and a willingness to see the other fellow's point of view. Some compromise in these visual matters is essential to public welfare.

The first step necessary is to make it possible for ophthalmologists to confer with optometrists without criticism. From there on, matters should not be too difficult. Leaders of both groups should meet without animosity, in friendliness, and on an equal footing and, bearing in mind primarily the visual welfare of the public, should iron out their differences. Naturally it will take a long time to eliminate all of the points of disagreement, but even this is possible and to make a good start in the right direction should not be hard. Most important is the point that coming to agreement is not a may, but a must!

Lawrence T. Post.

BOOK REVIEWS

HARVEY CUSHING, A BIOGRAPHY.

By John F. Fulton. Springfield, Illinois, Charles C Thomas, 1946. 722 pages, 150 illustrations, index. Price, \$5.00.

John F. Fulton, Sterling Professor of Physiology, Yale University, whose versatility matches that of his subject, has produced herewith a brilliant volume of biography that glows with admiration and affection for one of the greatest figures in medicine and surgery of all times. That this has been a labor of love and creative joy is obvious at the first thumbing of the book. Although an intimate friend of "the Chief," a close companion on many a fa-

mous occasion, and the literary executor of the Master, Fulton has written this splendid and vital work as objectively as was humanly possible for him to do. Throughout the book he refers to himself as "a friend" who said this or observed that, copying intentionally Cushing's own biographical method in writing the great *Life of Sir William Osler*. One cannot help but wonder whom J.F.F. has chosen to be his own literary executor and biographer, for surely the tradition that produced such magnificent biographies as "Osler" and now "Cushing" must be perpetuated and the torch handed on.

There are many physicians, surgeons, neurosurgeons, neurologists, and even ophthalmologists, for we honored H.C. (as Fulton calls him) by giving him the Herman Knapp medal from the Section on Ophthalmology of the A.M.A., in 1929, for his paper on the meningiomas that he presented before the Section, who will read this volume with great pleasure and profit. There will be countless medical students, house officers, residents, and internes who will try to take it apart to see what made the man tick, and some may even try to do back somersaults from hospital entrances throughout the world in emulation of the great man, trusting that some photographer may be present to snap the act for posterity.

It is not known whether or not Cushing was ever "analyzed" by a psychiatrist friend or foe to discover the driving force of his vital personality. He was fortunate in the choice of his forefathers, particularly so in his parents, for his father, made of stern stuff, still paid the freight of his extraordinary son until long past the usual age of paternal financial subsidy. Did he, realize in some prophetic fashion just what his son would do in life? Most doctor fathers of doctor sons want them to return as soon as training is over to help the old man in his work and speed

his retirement. Not so Dr. Henry Kirke Cushing, for if there were any parental objections to the long training program, the biographer does not make it clear.

A man of H.C.'s dynamic drive, ego, personality, and character could not but make enemies, most of whom were jealous perhaps, behind him in his march to the peak. He knew what he wanted and set out to get it, seizing the opportunities as they presented and squeezing the last ounce of juice from the fruit. His ruthlessness is lightly mentioned in the biography, but those who knew and recall him vividly to mind know how merciless he could be at times toward friend and foe alike.

The author of this review sat at his feet as a medical student and recalls many an occasion when this unpleasant trait of ruthlessness revealed itself in the classroom and operating theater. H.C. was a man possessed by a demon of perfectionism. His class-room humor could be and often was sardonic and sarcastic. He drove the students to despair in his quizzes by his remarks. Even his nephew Pat, was not spared these quips, and H.C. would turn on him like a tiger when the perfect answer was not forthcoming, as it almost never was from any of us. On other rare occasions, particularly when he was discussing and showing some of his collection of old medical books, all was sweetness and light, good humor and kindness. We did not know until after graduation what a great man this little devil really was, and perhaps it was presumptuous of us to expect anything else, worms that we were, but verbal scourgings and tongue lashings for our colossal and abysmal ignorance. But we learned much from this man and are grateful to have touched the hem of his operating gown in passing.

His iron character revealed itself most strikingly when, informed of his eldest son's tragic death in a motor accident, he

made the necessary arrangements by telephone for the bringing home of the body, and then went into the operating room where he calmly did a tedious and painstaking brain operation. Did his hand shake, or his heart turn sick, or his respiration increase, or his spirit falter? No one knows.

He was fortunate in the devotion of his wife who coped with his drive in life and surrounded him with every protective device she could, as if realizing that he did not belong to her or the children but to the world itself. One wishes that the author of the biography had devoted more space to the drama of this Spartan widow and her tribulations as wife of a genius.

There is much in the book of ophthalmic interest, particularly one gem. When on a visit to Lyons in 1900, H.C. called on Louis Dor. He said in his diary: "Dor is an ophthalmologist but such a one as the following description will relate. He took me to see a patient who had lost his cornea and ant. chamber from a hot iron. The man came to Dor after 8 days just as the slough had separated. The lens fell out and iris was prolapsed. Dor replaced them, covered the wound with a graft of a rabbit's whole cornea which he sewed in place and covered with one of the thin glass arrangements for astigmatic eyes. I saw the man 8 days after this—graft taken—slightly opaque. Probably will have vision." Did the graft really take? There is doubt about that for ophthalmic literature is silent, as far as I know, about this remarkable case. Had this operation taken place in the United States in the year 1946, the newspapers would have told us everything except the end results too, you can be sure.

In 1911 Cushing "persuaded Clifford Walker of the present graduating class (at Hopkins) to stay and work on ophthalmological problems in the Hunterian Laboratory and in the hospital next year. I

hope he will make good." Walker did make good with Cushing as is well-known, for when the latter moved on to Harvard he took Walker with him and used him to study the perimetric deviations in brain-tumor lesions particularly those of the pituitary. Clifford Walker remained with him for some time and then moved out to the West Coast returning periodically to the Brigham Hospital to check, at H.C.'s request, the perimetric procedures. One wonders why Walker left and why he discontinued to a large extent his interest in perimetry, unless it was his great absorption in the problem of retinal detachment. Incidentally, Walker rendered an unconscious disservice to ophthalmology, for Cushing, and his pupils and his followers, seldom, if ever, relied on an ophthalmologist's perimetry, preferring to do it themselves, even to this day. Surely, there were ophthalmologists in Boston capable of taking an accurate field of vision, sparing Walker a long trek East. This is a curious thing, and not even hinted at in the biography. Is there an untold story here of animosity to Boston ophthalmologists? I think it to be but another manifestation of the perfectionist wanting control over everything that related in any way to his field, and jealously guarding his prerogative.

This book has given such pleasure in its reading that one is reluctant to put it down for within its pages are revealed the life's activities of a man of his own time, who made his own time through hours and hours of meticulous, painful work in the library, laboratory, wards, and operating room. He seized Time by the forelock and made him do his bidding. With malevolent and dictatorial charm he wove the fabric of his long life into a cloth of gold of priceless worth. His keen eye, skilled hand, and trained brain founded a new school of surgery. His influence will be ever felt, like the visible light of a star that perished

thousands of years ago. This little man of steel sinews possessed such vital force that the storms of nature and human ills buffeted against him in vain until the very end. His life belongs to the world and to humanity and we have much to learn from him. We are grateful for the glimpse of an epic life that J.F.F. has so skillfully given us.

Derrick Vail.

WHY PUPILS FAIL IN READING.

By Helen M. Robinson, Director of the Reading Clinic, University of Chicago. University of Chicago Press, 1946. Price, \$3.00.

Approximately the first half of this book is a comprehensive review of the literature. It is unfortunate that the author was unable to include the more recent publications, probably due to the difficulty and delay in getting material published immediately.

The remainder of the book deals with the findings which are present in 30 selected cases of reading difficulties. An extensive investigation was made by various specialists in their respective fields to include psychometric and educational examinations, social history, psychiatric studies, pediatric examinations, neurologic examinations, visual examinations, examinations of hearing, speech examinations, and endocrine examinations.

In conferences after evaluating and correlating the findings, the patients were classified by the way of a summary: (1) Anomalies found by the individual examiners. (2) Factors considered important by the group. (3) Probable cause.

The general approach in the remedial work was to begin with the symptoms which were considered as the primary causes and postpone the attempt to correct the various other factors as presented. Unfortunately, due to circumstances be-

yond control, the author was unable to make a complete analysis of many of her cases. It was therefore impossible to demonstrate the growth curve of the entire group. As demonstrated in many of the cases, it was difficult to get satisfactory results by treating only one factor which was considered to be the primary cause, rather than by treating concurrently the entire group of symptoms as presented.

In general, this thorough piece of work on the problem of reading difficulties, like all similar work, opens more problems than it solves. This book should be available to all persons interested in the problem of reading difficulties.

George E. Park.

CORRESPONDENCE

CONTUSION CATARACT OF THE ANTERIOR LENS CAPSULE.

Editor,
American Journal of Ophthalmology:

I have just read Dr. Herbert F. Sudran-ski's interesting paper upon "Contusion Cataract of the Anterior Lens Capsule" (*American Journal of Ophthalmology*, 1946, volume 29, October, page 1281). His explanation of this "new" form of cataract is very intriguing, but I am afraid that this exhaustive study in intraocular dynamics is quite out of order since there is no doubt whatsoever, either from the description or from the photograph, that he is dealing with the extremely characteristic "Sunflower of Chalcosis Lentis," or the so called "Sonnenblumstar." The photograph is so typical that I am enclosing one of my own—a typical sunflower cataract, in order to accentuate the resemblance. Furthermore, I wish to refer to an article written in the Archives of Ophthalmology, 1944, volume 32, July, pages 63-65, in which this type of lens opacity was photographed. In this article

the technique of photography for such a cataract was described and, since the article dealt with "Chalcosis Lentis," such a

(Rosen). A typical sunflower cataract.

possibility should have occurred to the author.

It would appear that some retraction of the statement, "This lenticular opacity appears to be a unique variety of traumatic cataract not yet reported in the ophthalmic literature," is in order for this lens change is far from "unique."

Once having assumed that this is the sunflower cataract of Copper, it is not difficult to understand: (a) the biomicroscopic picture—that is, "complete reproduction of the circular sphincter muscle fibers and the radial pattern of the iris—on the anterior capsule of the lens—in faint, grayish-white markings," (b) the vitreous disorganization, (c) future course of the foreign body.

I trust that this brief note will be of some small value in maintaining the high caliber of the Journal and at the same time will be of some value to those young men who have not been fortunate enough to observe the "sunflower cataract" under the slitlamp.

(Signed) E. Rosen,
Newark, New Jersey.

Editor,
American Journal of Ophthalmology:

The photograph (minus data) sent to you by Dr. Rosen of Newark, New Jersey is, indeed, striking in its likeness to my case of contusion cataract recently published in the Journal. I am, however, unable to agree with Dr. Rosen that my case is actually one of sunflower cataract due to chalcosis.

Dr. Rosen referred to an article published in the Archives of Ophthalmology, July, 1944, which proved to be a case report of chalcosis authored by Dr. Rosen. The illustration of the sunflower cataract in that case bears only superficial resemblance both to the photograph sent to you by Dr. Rosen and to my own case. The first footnote in this article refers to a publication by Cordes and Harrington in the Journal, 1935, volume 18, page 348, which gives the following description of the typical sunflower cataract of chalcosis:

"The characteristic picture of chalcosis, as a rule, begins to appear several years after the introduction of the foreign body. There is present on the lens a disciform opacity occupying the pupillary area. It is greenish gray in color and rather metallic in appearance. In marked cases, the color may be a definite green. The edges of the ring are often serrated, with lines radiating to the periphery of the lens."

In his reported case, Dr. Rosen de-

scribed the cataract as "bluish green" or "aquamarine" in color. Such descriptions of the sunflower cataract of chalcosis that I have been able to find, similarly describe it as discoid in shape and of metallic color. Furthermore, chalcosis is found almost exclusively in cases of accidents involving ammunition (as in Dr. Rosen's case), and the development of chalcosis is concomitant with absorption of the foreign body.

My case of contusion cataract showed no evidence of a foreign body of copper. It was not a case involving an accident with ammunition. There was X-ray evidence that absorption of the foreign particles had not occurred. The cataract, upon the anterior lens capsule, in neither shape nor color, resembled the classic description of the sunflower cataract of chalcosis. There was no evidence of chalcosis of the cornea or other degenerative change due to the toxic effects of copper.

While I am unable to concur with Dr. Rosen's opinion of the significance of my case, I am deeply grateful for his having called to my attention a second case of contusion cataract, for surely a penetrating injury of the eyeball with a foreign body of copper should prove to be as efficient as any other in effecting such a lesion of the anterior lens capsule.

(Signed) Herbert F. Sudranski,
Indianapolis, Indiana.

LESLIE DANA MEDAL*

PRESENTATION TO HARRY S. GRADLE, M.D.

BY

CONRAD BERENS, M.D.

Mr. Chairman and Friends of Harry Gradle:

It is particularly fitting that the Saint Louis Society for the Prevention of Blindness should have selected the time of a meeting of the American Academy of Ophthalmology and Otolaryngology for the presentation of the Leslie Dana Gold Medal for outstanding work in the cause of preventing blindness. In the first place, every woman and man here not only is a friend of Harry Gradle but loves him because of respect for him personally and in appreciation of his work and his numerous activities, most of which had Prevention of Blindness implications.

Dr. Gradle or "Harry," as he is affectionately called by every member of the Academy, has been indefatigable in his work for this Society, and the postgraduate educational program and the Home Study Course have been important factors in educating ophthalmologists in this and other countries. His constant efforts to educate ophthalmologists have added new methods of prevention and treatment of eye disorders which undoubtedly have prevented much blindness.

Because of his researches, his writings, his teachings, his organization of the Pan-American Association of Ophthalmology, his imagination, and stimulating influence in conducting the affairs of his many activities, he has been a great leader in the Prevention of Blindness movement. No ophthalmologist today more richly deserves the honor of being awarded the Leslie Dana Medal. It is my privilege, on behalf of the Saint Louis Society for the Prevention of Blindness and The Association for Research in Ophthalmology, to present the Leslie Dana Gold Medal for the Prevention of Blindness to Dr. Harry S. Gradle. In his absence, because of illness, the medal will be received by Mrs. Audrey Hayden Gradle, who is equally outstanding in Prevention of Blindness activities. May I read the inscription?

"Let the light remain to Harry S. Gradle, distinguished ophthalmologist and teacher, ardent worker for saving sight."

Mrs. Gradle, will you take this medal to your husband with our deep love and fondest wishes for his speedy recovery?

* Presented at 1946 Chicago meeting of the American Academy of Ophthalmology and Otolaryngology.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

CRYSTALLINE LENS

Orr, H. C. Ray Cataracts. Trans. Ophth. Soc. U. Kingdom, 1944, v. 64, pp. 249-252.

Ray cataract, a term applied to lenticular opacities commencing in the posterior layers of the lens include the cataracts of glass blowers, puddlers, chain workers and those induced by ultraviolet and infrared rays, Roentgen rays, radium, lightning, and electric flash.

The author quotes Butler who stated that "the presence of lenticular opacities and of reduplication of the posterior capsule are not in themselves pathognomonic of glassblowers' cataract, but when, in addition, the slitlamp shows some detachment of the zonular lamella then the surgeon may go into the witness box and swear that the condition present is due to heat radiation and to no other cause." The incidence of the disease is less than it was 25 years ago owing to improved methods of work.

Such a cataract may develop within three months after operation for de-

tached retina when the diathermy point has been placed less than 13 mm. from the limbus. Presumably degenerative changes in the ciliary body induced by heat interfere with the nutrition of the lens capsule. Beulah Cushman.

Pignalosa, Giuseppe. The oxidation of some fatty acids and esters of fatty acids from the lens of guinea pigs on scorbutigenous diet. Boll. d'Ocul., 1944, v. 23, Oct.-Dec., pp. 243-256.

In 63 percent of guinea pigs kept on such a diet for 18 to 23 days, small punctiform anterior or posterior cortical or perinuclear opacities appear. These lenses can oxidize fatty acids or esters like many other tissues can. (Bibliography.) Melchior Lombardo.

Poyales, A. The Smith operation. Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, June, pp. 456-464.

Poyales believes that the Smith technic is being unjustly discarded, and that it has definite advantages in selected cases. The technic is described in detail, and intumescent cataract considered its chief indication. It is con-

tra indicated in high myopia, and in small cataracts in old people, in whom the eye becomes very soft after the section. In contradistinction to other methods of cataract extraction, marked hypotension is not desirable with this technic. The author attributes complications to faulty technic.

Ray K. Daily.

Poyales, A. A modification of the Smith operation. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, June, pp. 464-466.

The modification consists in delivery of the lens without tumbling. Poyales compares this delivery of the lens to the escape of a cherry kernel, when the cherry is squeezed by the fingers. The role of the fingers is exercised by a hook and the posterior lip of the incision. The hook is applied at the lower third of the cornea, and pressure exerted upwards and backwards, at an angle of 45 degrees with the optic axis. Poyales insists on extraction of the capsule after the lens has been delivered extracapsularly because of accidental rupture of the capsule. Considering the state of opacification in which lenses are extracted today, an extracapsular extraction is, according to Poyales, a surgical absurdity.

Ray K. Daily.

Reynolds, J. S. Cataract extraction under sodium pentothal. *Minnesota Med.*, 1946, v. 29, July, p. 700.

The author reports 100 consecutive cataract extractions under sodium pentothal without any unsatisfactory results. The eye is very much at ease, there is good lid relaxation, lid retraction is perfect, and there is no need for conversation with the patient. Dilation of the pupil is almost complete. The

patient is quiet when he leaves the operating room and remains so from one half to four or five hours.

John B. Hitz.

Ribeiro, Rufino. The history of aspiration in cataract extraction. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, June, pp. 434-447.

Ribeiro traces the application of suction in cataract extraction from Tsabet Ben Gorra, who lived in Irak in the ninth century to Barraquer's modern procedure. For successful application of the modern instrument the size of the suction cup and the degree of vacuum should be individualized according to the hardness of the lens, the size of the pupil, and the resistance of the zonule. Obviously the same cup with a set vacuum is not suitable for all types of cataract. The harder the cataract the smaller should be the cup and the greater the suction. The soft intumescent lens requires a cup with a large surface and low degree of suction. In order to avoid dislocating the lens care should be taken that the cup is firmly applied to the lens surface before suction is initiated. Suction should be abandoned at the slightest appearance of vitreous. To loosen the attachment between the lens and the hyaloid the lens should be rotated about its horizontal meridian, as advocated by the Greens. The delivery of the lens should be assisted by Smith's maneuver with a forceps applied at the lower limbus, and advanced over the cornea, so that when the lens is completely delivered the corneal flap is in its place and the wound is closed.

Ray K. Daily.

Samuels, B. Cataract associated with intraocular tumors. *Arch. of Ophth.*, 1946, v. 35, April, pp. 366-383.

The condition of the lens is described in a study of 57 globes containing intra-ocular tumors, 34 malignant melanomas, 21 retinoblastomas and one each of epithelioma of the ciliary body and of sarcoma. Folds of the lens capsule were infrequent, possibly because most of the globes were glaucomatous. Proliferation of the lens capsule was not a characteristic but there were instances in which the restricted proliferation showed unusual features. Necrosis of the subcapsular epithelium was observed in malignant melanomas along with necrosis of the tumor. This change was a rarity in retinoblastoma. Direct contact of the tumor with the lens seldom interfered with the transparency of the lens nor was dislocation a feature. Cataractous changes were frequently noted in the anterior and posterior cortex whereas the equator was less often affected. Calcification of the lens substance was observed in three cases of retinoblastoma. Other less striking features are discussed as well as aspects of clinical diagnosis of tumors associated with cataracts. (16 illustrations.) John C. Long.

Sasiain, M. R. The metabolism of the lens. *Arch. de la Soc. Oft. Hisp-Amer.*, 1945, v. 5, April, pp. 273-287.

The author reviews the literature and gives the following summary: The metabolism of the lens takes place through an electrotonic interchange in an anoxibiosis. The catalytic enzymes and the systems of oxyreduction are indispensable for the metabolism of the lens. Transparency of the lens and accommodation the the two principal functions dependent on the lens metabolism. To maintain normal lenticular transparency and accommodation the reduction power of the lens has to

reach and maintain a certain level. If the metabolic harmony of the lenticular constituents is lost, they precipitate, causing opacification of the lens.

Ray K. Daily.

Sedan, J., and Sedan-Baubys, J. Preliminary micropuncture in certain cataracts. *Ann. d'Ocul.*, 1946, v. 179, no. 1, pp. 35-40.

In milky cataracts and in some other types in which the capsule cannot be easily grasped with capsule forceps, a peripheral iridectomy is performed. The upper periphery of the lens is punctured as near the equator as possible with a fine needle. A small amount of milky lens matter exudes which facilitates grasping of the capsule with smooth capsule forceps preparatory to removal of the lens in its capsule.

RETINA AND VITREOUS

Amat, M. M., and Enciso, M. M. External exudative retinitis, or Coats' Disease. *Arch. de la Soc. Oft. Hisp-Amer.*, 1945, v. 5, Aug., pp. 623-630.

The authors describe the left eye of an 8-year-old girl, that had typical changes at the posterior pole as well as peripheral angiomas mostly in the inferior temporal portion of the retina. The general examination was negative, except for an eosinophilia of 6 percent. The literature on the pathogenesis of the affection is reviewed, and it is pointed out that neither Leber's theory of fibrinous exudation with subsequent degeneration of retinal tissue, caused by toxins that arise in small microbial emboli of low virulence, nor the modern conception of an endocrine disturbance that affects the permeability

of the capillary endothelium have any experimental support. (2 colored illustrations.) Ray K. Daily.

Azzolini, U., and Longo, P. Tortuosity of the retinal vessels considered as a part of a general vascular malformation (*Hamartosis vascularis diffusa*). *Riv. di Oftalm.*, 1946, v. 1, p. 35-51.

The authors review numerous case reports from the literature and add one of their own to show that tortuosity of the retinal vessels may be considered as a part of a general vascular anomaly. The name *hamartosis vascularis diffusa* is proposed (from the Greek *hamartanein*, to miss). Albrecht coined the term *hamartoma* for a developmental anomaly of a tissue which still remains identifiable with its physiologic structure and does not assume autonomous and destructive growth; the authors extend the expression *hamartosis* to denominate a congenital anomaly affecting the whole vascular system. Their patient, a woman aged 42 years, had telangiectases in the palpebral conjunctivas, in the fingernail folds and in the bladder, and a very pronounced retinal vascular tortuosity. They believe that the syndromes of Hippel-Lindau, Osler-Rendu, Sturge-Weber, Coats, and Groenblad-Strandberg all are related phenomena, due to a congenital anomaly of the mesenchymal system, particularly of the encephalo-chorio-retinal vascular tissue. (8 figures, bibliography.)

K. W. Ascher.

Barraquer Moner, José-I. A speculum (*Ecarteur*) for operation of detached retina. *Ophthalmologica*, 1946, v. 111, Jan., pp. 61-64.

The author recommends three instruments to be used in the operation for detachment of the retina instead of the lid speculum: a forked double muscle hook that can be slipped under two adjacent rectus muscles; a simple hollowed hook which is needed in introducing the former and a spoon-shaped spatula that is introduced into the orbit and serves as a retractor.

The advantage of these instruments lies in the fact that the cornea is protected by the eyelids during the operation. (1 photograph, 3 drawings, bibliography.) F. Nelson.

Cutler, N. L. Transplantation of human vitreous. *Arch. of Ophth.*, 1946, v. 35, June, pp. 615-623.

A technique is described for the transplantation of human vitreous from one eye to another. From 1.5 to 2 cc. of vitreous is aspirated from the recipient eye through an equatorial scleral incision using an 18 gauge needle and 2 c.c. of vitreous from the donor eye is then injected through the same needle. Three eyes in which this procedure was utilized are reported in detail. All three had old vitreous hemorrhage. In two of them the operation was successful with a decided reduction in the opacity of the vitreous. In the third there was failure, probably because of an old retinal detachment and a recurrent vitreous hemorrhage. There was a moderate reaction after the procedure, but no evidence of a foreign protein reaction was noted. The tension of all three eyes returned to normal within a reasonable period and remained normal. The blood group does not appear to be significant. (References, 1 figure.)

John C. Long.

Elwyn, H. Heredodegenerative diseases of the retina. *Arch. of Ophth.*, 1946, v. 35, June, pp. 662-669.

Heredodegeneration is used to designate diseases of the central nervous system which in the main are characterized by a specific loss of neural tissue as a result of hereditary influences. These diseases may be classified according to the conditions under which they are found or according to the anatomic structure involved.

Diseases originating in Bruch's membrane include disciform degeneration of the macula and angioid streaks in the fundus. Hyaline bodies originate in the pigment epithelium. Among the numerous diseases of the neuroepithelium are macular degeneration of various types, retinitis pigmentosa, retinitis punctata albescens, congenital night blindness, color blindness, gyrate atrophy, and choroideremia. Disorders of the ganglion cells give rise to Tay-Sachs disease, juvenile type of amaurotic familial idiocy, and Niemann-Pick disease. Involvement of the nuclear layers produces peripheral cystoid degeneration and widespread cystoid degeneration, forming the basis for rupture of the retina with hole formation. Retinitis circinata also originates in the nuclear layers. Tuberous sclerosis is a widespread heredodegenerative disease causing the production of abnormal cells and tumors in the nerve fiber layer. Feigenbaum, A., and Kornblüth, W. Intravitreal injection of penicillin in a case of incipient abscess of the vitreous following extracapsular cataract extraction. Perfect cure. *Ophthalmologica*, 1945, v. 110, Nov.-Dec., pp. 300-305.

A case of abscess formation in the vitreous following extracapsular cataract extraction and its complete cure by intravitreal injection of penicillin is described. The adjuvant value of subconjunctival injections in overcoming the infectious process is stressed. The probability of synergistic action from the simultaneous use of sulfadiazine is mentioned. (References.) F. Nelson.

Filatov, V., and Verbitska, V. Treatment of retinitis pigmentosa. *Am. Rev. Soviet Med.*, 1946, v. 3, June, pp. 388-394.

The injection of cod liver oil in retinitis pigmentosa produces a rapid improvement. In some instances effects are noted after one to two injections.

Increase in light sensitivity can be obtained by intramuscular injections of cod liver oil and by other methods in retinitis pigmentosa. The increase in light sensitivity after cod liver oil treatment is superior to other methods used. For example, when the Lauber method was used, the increase of light sensitivity was not more than 10 times in only one out of five cases. When retinol was used, there was an increase of 10 to 15 times only in five patients out of 12. Twelve cases of retinitis pigmentosa were treated by parenteral administration of cod liver oil, and in one patient there occurred an increase in light sensitivity of 1000 times, in another an increase of 50 times, and in five cases an increase of 10 times.

Effects produced by the use of cod liver oil were observed in very severe, chronic forms of the disease.

On the basis of these observations it can be said that the parenteral use of cod liver oil in the treatment of reti-

nititis pigmentosa is very effective and deserves further study.

The authors' cases of retinitis pigmentosa, treated with injections of cod liver oil, could not be followed for a long enough period. It is still too early to judge results. Further observations might indicate prolonged treatment or repeated injections at intervals.

Filatov thinks that cod liver oil acts not only through its vitamins, but also through other liver by-products. He worked with the transplantation of preserved tissues, such as skin and conjunctiva, and showed the effect of these products. In order to verify the mode of action of cod liver oil, a small piece of human liver preserved at a low temperature was implanted under the skin of a patient with retinitis pigmentosa.

Theodore M. Shapira.

Filatov, V. **Retinitis pigmentosa.** *Am. Rev. Soviet Med.*, 1946, v. 3, June, pp. 395-396.

Favorable results have been obtained in retinitis pigmentosa after implantation of preserved vascular membrane or placenta under the conjunctiva on the trephined sclera. Similar effects followed implantation of liver under the skin of the abdomen, transplantation of preserved skin to the head or the abdomen, and injection with cod liver oil.

Treatment by injection of cod liver oil was given to 60 patients; in 8 there was no effect; in 52, improvement was noted subjectively and during functional examination of the patient.

The patients showed heightened visual acuity, often to 0.2 to 0.3, and sometimes to 0.5 to 0.6. There was improvement also for close reading. The field of vision was widened 15 to

20 per cent, both peripherally and in the center, so that sometimes there remained only annular scotoma, which was sometimes incomplete. Moderate improvement in dark adaptation was also observed. Sometimes it was considerable and in individual cases complete restoration was noted.

Another important finding was decrease and even complete disappearance of photopsy which was apparently first established as a symptom of retinitis pigmentosa by Verbitska.

In the majority of the patients improvement of visual functions occurred after the first 4 to 10 injections of 0.5 c.c. each, and in some after 15 to 25 injections. Improvement of functions does not stop after discontinuing injections, and may persist for a few weeks. After several months the functions may regress, but can be restored by repeated courses of cod liver oil or additional tissue transplantations.

Implantation of placenta under the conjunctiva was made in 22 patients; implantation of placenta was also performed subcutaneously in six. In these 28 patients the results obtained were approximately the same as those with cod liver oil, namely a marked improvement in 22. Implantation of preserved liver under the skin gave a significant and prolonged effect in four out of five patients. Transplantation of skin produced an effect in 7 of 17.

It is apparent that the fight against retinitis pigmentosa, which seemed hopeless, is nevertheless possible; and modern ophthalmology need not confine itself to the recording of retinitis pigmentosa nor need it reconcile itself to the inevitable blindness.

Treatment by implantation of preserved tissues and by intramuscular injections of cod liver oil, singly or in

combination, is a most effective method for the treatment of retinitis pigmentosa. It does not lead to cure, but aids the handicapped by restoring work capacity. Theodore M. Shapira.

Filatov, V. P., and Verbitska, V. A. **Implantation of preserved placenta in retinitis pigmentosa.** *Am. Rev. Soviet Med.*, 1946, v. 3, June, pp. 397-398.

The favorable effect obtained in retinitis pigmentosa by parenteral administration of cod liver oil depends, according to Filatov, not only on the contained vitamins, but also on the disintegration products of the liver formed during its preparation. Improved retinal functions observed after implantation of preserved liver in retinitis pigmentosa confirm this supposition. However, Filatov held that the influence of preserved liver on the retina is not specific and that other preserved tissues also can produce such an effect.

Three cases of retinitis pigmentosa are presented here in which implantation of preserved placenta was made.

The case histories cited show that implantation of placenta in retinitis pigmentosa gives encouraging results. A prolonged period of observation is necessary for proper evaluation of this therapeutic measure.

Theodore M. Shapira.

Filatov, V. P., and Verbitska, V. A. **Implantation of preserved liver.** *Am. Rev. Soviet Med.*, 1946, v. 3, June, pp. 398-399.

Several cases of retinitis pigmentosa were treated by intramuscular injections of cod liver oil with good results. Filatov thinks that the active principle of cod liver oil is the byproduct of liver obtained during the extraction of oil.

The action of cod liver oil is analogous to the action of transplanted preserved tissue. To verify this supposition liver was implanted subcutaneously in cases of retinitis pigmentosa.

Two cases are presented in which such implantation was performed. In the cases cited implantation of liver caused definite improvement in retinal functions.

The cases presented are indirect confirmation of Filatov's proposal that the active principle of cod liver oil is the byproduct of liver disintegration.

Theodore M. Shapira.

Fritz, M. **The effect of cranial trauma on the retinal circulation in war injuries.** *Bull. Soc. Belge d'Ophth.*, 1945, no. 81, April 29, pp. 45-50.

The change in the retinal circulation following cranial traumatism in war injuries consists of an alteration in arterial tonus. The author points out that there is either a decrease in tonus, which is the usual case, or an increase in tonus, and occasionally it is possible to have a diminished and raised tonus simultaneously, affecting different arterial sectors in the same individual. The author also notes that a frequent change following cranial trauma is perivascular retinal edema, which is actually the factor responsible for the pathologic enlargement of the angioscotoma. He presents a case of a war wound in the parieto-occipital area, in which funduscopy revealed that the central retinal artery was abnormally constricted, although the nasal superior branch was dilated. M. R. Cholst.

Hazelton, A. R. **The nature of starvation amblyopia.** *J. Royal Army Med. Corps*, 1946, v. 86, April, pp. 171-178.

Of a group of 409 patients at an

Australian Army hospital, who complained of dimness of vision, 277 were classified as having "avitophthalmia," either active or inactive. The active group (156) presented symptoms which were classified in two groups: (a) eyestrain (exhaustion of ciliary muscle), and (b) retinal damage. In the former group, characterized by headache, pain in eyes, and heaviness of lids, marked improvement was obtained by administration of thiamine. The latter group was characterized by blurred daytime vision, photophobia, transient central scotoma, and changes in colors.

The author uses the Ladd-Franklin color theory to explain the reported color changes in terms of a deficiency of the photosensitive substance of the retinal cones. Administration of thiamine, nicotinic acid, and haliver oil had no effect upon these "retinal" symptoms.

Eight patients received, in addition to their regular diet, 10 raw eggs daily for 30 days. All eight were considered to have benefited from this dietary regime; one case was considered "cured."

Ibáñez Puiggari, M., and Malbrán, J. An apparatus for surgical treatment of retinal detachment. *Arch. Chilenos de Oft.*, 1945, v. 2, Nov.-Dec., pp. 7-13.

With detailed description and abundant illustration, the authors discuss an apparatus for use in connection with the detachment operation, including diathermy appliances, ophthalmoscope to be used during the operation, and other particulars. The whole apparatus is stored in a large metal chamber, capable of being hermetically sealed, using formalin tablets for sterilization, and attached to the wall by a bracket

permitting adjustment in the vicinity of the operating table. Detailed study of the original descriptions and illustrations is essential for understanding of the device. (6 photographs, full-page clinical drawing, references.)

W. H. Crisp.

Joly, J. P. A case of exudative retinitis (Coats). *Arch. d'Opht.*, 1946, v. 6, no. 1, pp. 46-48.

A case of unilateral exudative retinitis, considered to be Coats' disease, was observed in a young man of 19 years. The fundus lesion, which was in the upper temporal region, was complicated several weeks after onset by a cyclitis. Focal infection studies were negative. There was no family history of tuberculosis. Nonspecific therapy resulted in some improvement.

Phillips Thygeson.

Longhena, Luisa. Two cases of Intraocular cysticercus. *Riv. di Oftalm.*, 1946, v. 1., Feb., pp. 94-109.

One patient with a subretinal cysticercus cellulosa refused to undergo the proposed operation; in the other, the parasite was found in the vitreous and the eye enucleated. The pathologic findings are described. (8 illustrations, bibliography.)

K. W. Ascher.

Maeder, G. Hereditary hemeralopia and syndactyly. *Ophthalmologica*, 1946, v. 111, April-May, pp. 278-284.

Congenital severe hemeralopia and syndactylism of the toes were found in four generations of a family. The pedigree is outlined. Only one family member apparently was affected with both anomalies. The possibility of a lesion in the diencephalon and a relationship to the Lawrence-Moon-Biedl-

Bardet syndrome is mentioned. (3 figures, references.)

Alice R. Deutsch.

Maggiore, L. On the functional relations between the pigmented epithelium and the neuro-epithelial layer of the retina. *Ann. di Ottal. e Clin. Ocul.*, 1946, v. 73, Jan., pp. 3-16.

On the basis of studies and observations made by himself and others the author formulates three hypotheses to explain the partial persistence of visual function in the affected part of the retina in shallow detachments and in incomplete re-attachments of the retina.

1. The partial persistence of visual function may be due to the fact that the pigment-bearing processes of the pigmented epithelium—in the form of finely drawn-out filaments—may bridge the space between the pigmented epithelium and the neuro-epithelium. Only when the space between these layers exceeds a certain limit, so that it is no longer bridged in this fashion, does the affected part of the retina become absolutely blind. The progressive reduction in vision can thus stand in direct relation to the progressive decrease in these residual connections between the two layers.

2. It may also depend on the amount of fluid separating the two layers. If the amount is small, the concentration of substances originating in the pigmented epithelium may be sufficient to act upon the neuro-epithelium and thus assure a certain measure of visual function, whereas, if the amount of fluid exceeds a certain limit, the dilution, of the substances diffused from the pigmented epithelium may be so great that the neuro-epithelium is not affected by them. The subretinal fluid, either by its mere presence or by its chemical

constitution, may also affect the normal metabolism of the retina.

3. According to Schanz's theory, electrons liberated from the pigment cells by the action of light or originating in reactions between substances produced by the pigment cells and other substances contained in the rods and cones, play an essential part in vision. The partial persistence of visual function may be explained by the supposition that these electrons can act upon the rods and cones only when the thickness of the subretinal fluid does not exceed a certain limit.

None of these three hypotheses can be considered sufficient in itself to furnish an adequate explanation, but they are all in accord with the clinical observation that the visual function of the retina is retained to a certain extent in shallow detachments but is completely annulled in bullous detachments.

Harry K. Messenger.

Miranda, A. G. Acute hypotony in retinal detachment. *Arch. de la Soc. Offt. Hisp.-Amer.*, 1945, v. 5, Aug., pp. 664-672.

The literature is reviewed, and a case of this rare occurrence reported. The 56-year-old woman, with myopia of 20 diopters and a history of a loss of vision in the nasal part of the field of the left eye of two weeks duration, presented herself with violent pain and intense congestion in the eye. She had conjunctival chemosis, corneal cloudiness, turbid aqueous, a deep anterior chamber, an almost complete retinal detachment, and a detachment of the inferior nasal portion of the choroid. The tension was negative, and the eyeball was extremely sensitive to touch. Under atropine the acute symptoms subsided in six days, and the

choroidal detachment disappeared. The pathogenesis of the phenomenon is discussed, and it is pointed out that the presence of the ciliary injection, the turbid aqueous, and the pain indicate the presence of a cyclitic process. Possibly the products of disintegration of some of the constituents of the sub-retinal fluid were the cause. The detachment of the vitreous so frequent in retinal detachment, through retraction of the iris and lens may have produced the deep anterior chamber. Functional circulatory disturbances, and scleral dehiscences with escape of the intraocular fluid are also factors to be considered in the genesis of acute hypotension in some cases. Since the use of a compressive bandage in the treatment of retinal detachment has been abandoned, cases of acute hypotension are encountered rarely. (Visual field.)

Ray K. Daily.

Monnier, M., and Amsler, M. **Objective examination of the function of the retina with the electroretinogram in a case of concentric contraction of the visual field.** *Ophthalmologica*, 1945, v. 110, Nov.-Dec., pp. 225-241.

After an accident without direct injury to the skull a patient had various subjective and objective encephalopathic symptoms. Among them were mouches volantes, fatigability during reading, insufficiency of convergence, "accommodtonie", diminution of the central visual acuity, and concentric narrowing of the visual field, with occasional variations from day to day but never larger than 60° on the temporal side and 35° on the nasal.

Electroretinograms showed that the retina had a normal, if not increased receptivity, even in the peripheral, apparently blind parts of the fields.

Furthermore, the considerable amplitude of the positive potentials, particularly of the b_+ potential, seemed to indicate that the retinal excitations were normally discharged in the optic nerve.

On the basis of these electroretinographic data, one would have expected the patient to be dazzled and to present exaggerated blinking reflexes but he behaved as though the retinal excitations, normally discharged in the optic nerve, did not reach the visual centers and the motor centers of the blinking reflexes. Since the first optic neurones functioned normally, as proved by the electroretinogram, it must be assumed that the optic excitations were stopped either at the level of the mesodiencephalic synapses (superior, colliculus lateral geniculate bodies), or at the level of the optic neurones in the occipital center. The evidence and localization of such synaptic stoppage are discussed in the light of experimental and clinical data. The physiopathology of the concentric narrowing of the visual field and the partial loss of the blinking reflex are also discussed. (References, photograph, 1 table, diagrams, visual fields.)

F. Nelson.

O'Malley, C. L. **Retinal hemorrhage with vitreous clouding in young adults (Eales' disease).** *Trans. Ophth. Soc. U. Kingdom*, 1944 v. 64 pp. 261-269.

The author describes four patients with recent vitreous hemorrhages. The oldest patient was a woman 36 years of age and the other three were young men 22, 29, and 30 years of age.

He divides the disease into four distinct stages. In the first stage small round hemorrhages are seen scattered in the periphery and related to the small end twigs of the venous branches

and there is low intraocular tension. In the second stage there is leakage of blood and plasma from the larger venous branches into the pre-retinal plane with associated vitreous clouding. Vision is not affected. In the third stage main trunks are involved. Blood and exudate leaks along vessels and into the vitreous which becomes densely clouded. Vision is reduced and ocular tension increased. In the fourth stage the fundus shows the scars of many attacks with permanent vitreous clouding and vascularized fibrous tissue bands. Ocular tension is increased. Eales' disease has many characteristics of an allergic response. The specific lesion is a peripheral endophlebitis associated with a sex-linked hormone.

Beulah Cushman.

Redslob, E., and Bronner, A. **Retinal hemorrhages in senile purpura and glaucoma without hypertension.** *Ann. d'Ocul.*, 1946, v. 179, no. 2, pp. 64-70.

This unusual combination of degenerations was observed in a woman 74 years of age. Intraocular hemorrhages with absorption followed cataract extraction in both eyes. Concurrent hemorrhages appeared in the skin, especially near the elbow. Upon excision the skin showed absorption of the elastic tissue which resulted in enlargement of the capillaries and subsequent hemorrhage. Blood tests and other examinations were essentially negative.

The author reasons that intraocular hemorrhage and glaucomatous excavation with hypotension were due essentially to constitutional presenile degeneration which involved the absorption of the elastic tissues in and about the vessels and in the papilla. Secondary capillary dilatation with oc-

casional transient hypertension presumably caused the hemorrhages.

Charles A. Bahn.

Regoli, Attilio. **Angioid streaks of Knapp with cardiovascular changes.** *Boll. d'Ocul.*, 1944, v. 23, Oct.-Dec., pp. 209-228.

A man, 35 years of age, and recently affected by marked diminution of vision in both eyes, showed the classic picture of angioid streaks of the retina with a diffuse chorioretinitis of the macular and perimacular regions in both eyes. The general examination revealed changes in the cardiovascular system as evidenced by a mitral murmur and slight hypertension. The cardiovascular changes have great importance from a diagnostic point for these general changes are associated with changes of the elastic tissue. The retinal streaks are not to be considered a distinctive entity but as part of a complex syndrome that results from a dystrophy of the elastic tissue of degenerative origin. In this patient there was no elastic pseudoxanthoma of the skin, therefore this disease represents an incomplete syndrome of systematized elastorexis. (Bibliography.)

Melchior Lombardo.

Rønne, Gerhard. **Local treatment of intrabulbar infections. General Considerations.** *Acta Ophth.*, 1944, v. 22, pt. 1, pp. 95-104.

Rønne discusses the general criteria for experimental investigation on the efficacy of intrabulbar injections. The isolation of the ocular contents by a thick capsule, the transparency of the media that permit observation of the intraocular process, and the non-cellular structure of the vitreous make the eye a sensitive and easily accessible

biological medium. The literature on experimental intrabulbar therapy is briefly reviewed, and the reasons for the lack of development of clinical intrabulbar therapy is discussed.

Santoni, A. Investigations concerning the index of refraction and the pH of the subretinal fluids in idiopathic retinal detachment. *Riv. di Oftalm.*, 1946, v. 1, Jan., pp. 3-14.

Subretinal fluids obtained during 33 detachment operations from 30 eyes were examined with the refractometer of Pulfrich and with the quinhydrone-electrode, if sufficiently large amounts were withdrawn. Fluids containing traces of blood were discarded. The index of refraction of fluids from eyes with a history of eight days to 25 months of retinal detachment, varied between 1,334 and 1,340; no definite relationship was found between duration of the detachment and refractive index. There was no correlation between the refractive index and the operative result. Santoni stresses the possibility of errors due to previous small hemorrhages into the subretinal fluid. The H-ion concentration varied from pH 7.45 to pH 8.00. Whereas the fluids having a pH of 7.67 to 8.00 were withdrawn from detachments of long duration, more recent detachments revealed readings as high as 7.73 and 7.8. He compares his results with those obtained by Weve and Fischer, and those of Contino, and discusses the retinal metabolism in normal and in diseased eyes. The shift to the alkaline side may be due to the production of ammonium and of other amines as suggested previously by Weve and Fischer.

K. W. Ascher.

Satanowsky, Paulina. Two cases of embolism of a branch of the central retinal artery with recovery. *Arch. de Oft. de Buenos Aires*, 1943, v. 18, Nov., p. 579.

Two cases of sudden and complete obstruction of a branch of the central retinal artery in elderly individuals with hypertension are reported. After treatment with acetylcholine and nicotinic acid the symptoms gradually disappeared and the ophthalmoscopic picture improved. The differential diagnosis of spasm and embolism is discussed with special emphasis on the perimetric findings. (Visual field charts, bibliography.) Plinio Montalván.

Schantz, E. M., Embree, N. D., Hodge, H. C., and Wills, J. H. Jr. The replacement of vitamin A₁ by vitamin A₂ in the retina of the rat. *J. Biol. Chem.*, 1946, v. 163, May, pp. 455-464.

The experiment reported in this paper was performed to determine the extent to which animals using vitamin A₁ (ordinarily referred to as "vitamin A") in their bodily functions could replace the A₁ with vitamin A₂. The livers of fresh-water fish have been found to contain vitamin A₂, a substance closely related to vitamin A₁, which is found in man and most other animals. These same fresh-water fish have a photosensitive retinal pigment different from the rhodopsin, or "visual purple," of human retinas. This pigment, called "porphyropsin," has an absorption spectrum which is distinct from that of rhodopsin.

In this experiment, albino rats were depleted of their normal vitamin A₁ stores, and then were fed diets containing only vitamin A₂ for twelve weeks. It was found that the visual

purple, or rhodopsin, normally found in the rats, had been replaced by porphyropsin (measured spectrophotometrically). Further, bleaching of the retinas of these rats produced no retinene, a substance normally found after the bleaching of rhodopsin.

Vitamin A₂ was stored in the livers of these experimental rats, just as vitamin A₁ is normally stored. In the blood, however, the vitamin A₂ level was built up very slowly, while the vitamin A₁ levels diminished little.

The authors concluded that vitamin A₂ could replace A₁ satisfactorily in many bodily functions.

Benjamin Milder.

Schmid, A. E. Relations of periphlebitis of the retina and recurrent juvenile hemorrhages into the vitreous to endangiitis obliterans. *Ophthalmologica*, 1945, v. 110, Nov.-Dec., pp. 259-291.

The author outlines the history of the subject and reviews the literature. He analyzes the examinations of the eyes of 86 patients with endangiitis obliterans of 25 patients with periphlebitis of the retina and juvenile recurrent hemorrhage of the vitreous.

Marchesani's contention that periphlebitis of the retina and juvenile hemorrhage of the vitreous are manifestations of endangiitis obliterans cannot be proved. Periphlebitis of the retina, juvenile recurrent hemorrhages of the vitreous, and the accompanying iridocyclitis are, if not exclusively, in the majority of cases due to tuberculosis. (2 tables, 3 curves, 2 Rontgenograms.)

F. Nelson.

Stenstrom, Solve. Retinitis centralis serosa. *Acta Ophth.*, 1943, v. 21, pt. 1-2, pp. 97-106.

This disturbance which frequently

occurs in Japan, is characterized by a circumscribed macular edema. It is thought to be rare in Europe, but the fact that five cases were seen at the Sahlgren eye clinic in one-half year suggests that perhaps these cases are not as rare as is believed, and that many are being overlooked. Stenstrom's five cases had no definite etiology, and he suggests that this may be a symptom complex of varied etiology and not a disease entity. That it may occur on a vascular basis is shown by one of his cases in which the macular lesion appeared in a hypertensive fundus. After a time the picture changed to that of a hypertensive retinitis.

Ray K. Daily.

Traquair, H. M. The nerve fibre bundle defect. *Trans. Ophth. Soc. United Kingdom*, 1944, v. 64, p. 3.

The author describes in detail the anatomy and vascular supply of the retina in order to clarify some of the questions which arise in the analysis of visual fields.

The fibres from the nasal half of the retina converge directly from the periphery to the papilla in a straight course. The temporal fibres lie in arches above and below the macular area. The arches extend from the raphé, which lies on the horizontal meridian between macula and periphery, to the papilla. On the papilla the fibres are gathered together to form a thick cushion, except in the temporal quadrant where the nerve fibre layer appears thinner and less vascular.

The term *nerve fibre bundle* refers to any small group of fibres which lie together as they enter the papilla although there is no anatomical segregation into such groups in the retina. Lesions of such a group near the

papilla cause a scotoma that corresponds to the area of fibres involved, and is wedge-shaped or cuneate, narrow near the blind spot and wider peripherally. Arcuate bundles consist of uncrossed and crossed fibres, and straight bundles are made up of crossed fibres only. The nerve fibre raphé ceases at the temporal edge of the fovea.

Retinal arteries have an arrangement similar to that of nerve fibres. The vascular twigs overlap the temporal half of the horizontal meridian above and below and follow a wavy line. Vessels often pass through the macula towards the papilla and may divide the macula horizontally. On the nasal side the arteries extend in a radial direction. The papillo-macular area may be wholly or partly supplied by a cilio-retinal artery. The optic nerve is nourished by small branches of the ophthalmic artery. The chiasma receives twigs from the adjacent vessels.

The nerve fibre bundle defect is recognized by its shape and is the result of any localized lesion which impairs the conducting power of a group of adjacent fibres. The most common are the lesions produced by glaucoma and the inflammatory focus of deep choroiditis. Other causes are vascular obstruction, foreign bodies in the retina, and retinal hemorrhages. The causal lesion may be situated in the visual pathway behind the eyeball as far back as the chiasm. When the field defect does not extend to the periphery it may be assumed that the whole thickness of the nerve fibre bundle is not affected.

Vascular obstruction may affect the functional efficiency in the retinal area of the distribution of the affected vessel because both ganglion cells and

nerve fibres are deprived of blood, and also because the nerve fibres at some distant point may be subjected to ischaemia and rendered non-conducting. The blind spot is usually separated from the scotoma by an area or bridge because of the double vascular supply of the retina adjoining the papilla.

Nerve fibre bundle defects with scotoma occur in every case of chronic simple glaucoma. The belief that enlargement of the blind spot is an early sign of glaucoma is based on inadequate observation. The scotomas may begin anywhere in the line of the arcuate fibres except at the edge of the blind spot; 60 percent arise in the upper part of the field and less than 40 percent in the lower. Straight cuneate defects on the temporal side of the blind spot are rare in the early stages. The temporal side of the blind spot appears to be lost by peripheral depression in quite a different manner from that on the nasal side.

The author does not feel that the piling up of the nerve fibres on the nasal side of the disc explains the characteristic scotoma as the upper part of the field may be completely destroyed while the lower is intact or vice versa. On the nasal side the nerve fibre layer is thick and has few blood vessels; on the temporal side the fibre layer is thin and the blood vessels very minute and it is here that the lesions are more frequently found. The invulnerability of the macular fibres is unexplained. Why the defect practically never begins at the equator of the disc on either side and why the field is lost on the temporal side in a manner quite different from that on the nasal side is not clear.

The slenderness of the nerve fibre bundle defect indicates a correspondingly narrow lesion. The growth of the

scotoma towards the blind spot would seem to indicate that it is the position of the affected nerve fibres in the retina that explains the phenomenon.

The fibre bundle defects of glaucoma remain an ophthalmologic puzzle; a study of the finer anatomy of the vascular supply to the fibres may be helpful.

The characteristic central scotoma of retrobulbar neuritis has been attributed to a special vulnerability of the macular fibres but the author feels that the fibres affected are probably selected on an anatomic basis.

Injury to the optic nerve due to a blow on the temple produces the bundle defect more often than retrobulbar neuritis and the damage is probably due to trauma to the small arterial twigs.

In bitemporal hemianopsia the bundle defect can be traced and the most plausible explanation of its characteristics is found in the arrangement of the nutritive vessels.

Definite nerve fibre bundle defects have not been found in lesions above the level of the chiasm.

Nerve fibre bundle defects are never found in toxic amblyopia or the amblyopia of squint. They are common in affections of the visual pathway between the retina and chiasm.

Vázquez Barriere, A., and Boado, L. A. Congenital folds of the retina. *Arch. de Oft. de Buenos Aires*, 1943, v. 18, Nov., p. 572.

Two cases of congenital folds of the retina are reported. In the first the fold, which coexisted with a persistent hyaloid artery, was related to the position of the fetal cleft; in the second there were no vestiges of the hyaloid

artery and the position corresponded to an inferior temporal sector between the three and five o'clock meridians. The literature is briefly reviewed. (Illustrations.) Plinio Montalván.

Weekers, Roger. Seasonal variations of the frequency of occurrence of idiopathic retinal detachment. *Ophthalmologica*, 1945, v. 110, Sept.-Oct., pp. 218-223.

Of 208 cases of idiopathic detachment of the retina 31 percent occurred in summer, 30 percent in spring, 20 percent in autumn and 18 percent in winter. Detachments caused by retinal or choroidal neoplasms or an inflammatory uveal process were eliminated from the statistical material.

Continued intensive solar radiation may be a factor in the development of detachment of the retina. There is reason therefore, to advise patients who are predisposed to this affection to avoid bright light and to wear dark glasses on sunny days.

F. Nelson.

Weekers, Roger. The cholinesterase of the retina. *Acta Opth.*, 1945, v. 23, pt. 2, pp. 161-170.

In this laboratory study extract of bovine retinas was used for the investigation of its cholinesterase content. The data show that it is present in the retina and optic nerve, and is one hundred times more concentrated in the retina than in the nerve. It is evenly distributed throughout the whole retina, equal weights of peripheral and central parts of the retina contain equal amounts of cholinesterase. Its action is inhibited by the injection of eserine into the vitreous. Retinal cholinesterase is stable and maintains its activity after

24 hours in the refrigerator. (Graphs.)

Wille, Herluf. Investigations on the influence of K avitaminosis on the occurrence of retinal hemorrhages in the newborn. *Acta Ophth.*, 1944, v. 22, pt. 3, pp. 261-269.

In a control material of 594 cases, retinal hemorrhages which left no trace after their absorption were found in 42.4 percent. The administration of vitamin K intramuscularly to 316 patients before the onset of labor reduced the incidence of hemorrhages in the infants to 31 percent. Administration of vitamin K after the onset of labor was ineffective. The literature is reviewed and the relation of retinal to cerebral hemorrhage in the new born is pointed out. (Illustration.) Ray K. Daily.

Zentmayer, W. Angioid streaks of the fundus oculi observed over a period of thirty-six years. *Arch. of Ophth.*, 1946, v. 35, May, pp. 541-545.

A brief abstract of the clinical history of a typical case of angioid streaks of the fundus oculi observed over a period of thirty-six years is reported. The case was presented before the American Ophthalmological Society in 1909.

A review of the literature on the pathology is given and the author concludes from present evidence that angioid streaks are probably due to degeneration of Bruch's membrane, in which ruptures occur. The hemorrhages that are seen at various stages of the disease result from similar lesions in the walls of the blood vessels and the destructive changes that occur in the macula later are part of the syndrome. The gray zone about the papilla may be a manifestation of the

changes in Bruch's membrane; it is the only layer of the retina or the choroid which reaches the optic nerve, and it is much thicker in this area than elsewhere. R. W. Danielson.

OPTIC NERVE AND TOXIC AMBLYOPIAS

Andersen, Borge. Some remarks on the inheritance of Leber's Disease. *Acta Ophth.*, 1944, v. 22, pt. 3, pp. 233-236.

The author evaluates the statistical data that support Lundsgaard's conclusions in her argument with Rønne. Ray K. Daily.

Broendstrup, Poul. Primary tumors in the optic nerve. *Acta Ophth.*, 1944, v. 22, pt. 1, pp. 72-94.

The literature is reviewed, and five cases are reported. Two of the tumors were oligodendrocytomas, and three were meningiomas. Characteristic of oligodendrocytomas is the occurrence of several types of glia cells in the same tumor. The structure of meningiomas is homogeneous. The prognosis, aside from loss of the eye, is good. The tumors do not metastasize, and have no tendency to recur. Therapy consists of removal of the tumor. (4 illustrations.) Ray K. Daily.

Bruetsch, W. L. Malaria therapy in syphilitic primary optic atrophy. *Jour. Am. Med. Ass.*, 1946, v. 130, Jan. 5, pp. 14-18.

Malaria therapy is conceded to be the most efficacious method of treatment of primary syphilitic optic atrophy. Routine treatment with arsphenamine, bismuth, and mercury is of no value. The best explanation is that malaria causes an arrest of the inflammatory phase of the neurosyphilitic process that goes

on within the optic nerves. Exactly how this occurs is unknown.

In favorable cases, one course only is needed. Tertian malaria is used. In patients who need another course, it is necessary to use the quartan type. Perhaps the addition of penicillin will prove of more value than therapy with malaria alone.

In patients who react favorably, there will be an expansion of the visual fields; in the others optic atrophy continues.

The relative uselessness of surgery is explained. (3 photographs, references.)

Faranier, G. **Severe optic neuritis from methyl alcohol intoxication.** Ann. d'Ocul., v. 178, 1945, Dec., pp. 528-530.

A man, 44 years of age, developed

permanent blindness, weakness, abdominal pain, and delusions after 15 drinks daily of 40 percent methyl alcohol for 16 days. During the first week the pupils were dilated and fixed, the fundus normal. Then a slight papilledema and permanent pallor of the disc became manifest. Charles A. Bahn.

Hultquist, G. T. **About aberrant fibers of the fasciculus opticus.** Ophthalmologica, 1945, v. 110, July-Aug., pp. 1-14.

The author contributes two cases of aberrant fibers of the optic fascicle. In one of them a nerve-fiber bundle left the main fascicle by way of two roots, one of them behind the entrance of the central artery of the retina and the other in the temporal inferior part of the fascia of the eye muscles. After a separate course the aberrant bundle again entered the optic fascicle in the chiasm. Fibers of pure glial tissue radiated from the aberrant bundle as well as from the main stem of the optic fascicle of both sides and ended blindly in the connective tissue of the dura. These fibers are fundamentally interesting, inasmuch as they show that optic fibers that end blindly do exist and that these fibers are not medullated. A second case is described in which a cone of medullated nerve fibers protruded from the ventral side of the chiasm, similar to one reported by Volland. The literature and classification of aberrant optic nerve fibers is discussed, A new classification, based chiefly on the presence or absence of myelin sheaths in the aberrant fibers, is suggested. Max Hirschfelder.

Lundsgaard, Ruth. **The inheritance of Leber's disease.** Acta Ophth., 1944, v. 22, pt. 3, pp. 227-232.

Lundsgaard criticizes Rønne's statistical procedure and believes that his conclusion as to inheritance of Leber's disease is erroneous. Rønne believes to have proved that the inheritance is cytoplasmic, while Lundsgaard believes that the germ for the disease is autosomal, almost completely dominant in the male, incompletely dominant in the female, and with a lethal action on the spermatozoa.

Ray K. Daily.

Magitot, A. The optic nerve and the message it carries. *Ann. d'Ocul.*, 1946, v. 179, no. 1, pp. 24-34.

The optic nerve is not a nerve but essentially a commissure which unites two cerebral areas. It contains visual and photomotor centripetal fibers, and also centrifugal fibers whose functions are not yet known. Its 500,000 to 800,000 fibers carry more impulses than the posterior sensory portion of the medulla because the optic nerve acts as a visual receptor for an estimated 130,000,000 rods and 7,000,000 cones. The smaller and more numerous visual fibers are about 2μ in diameter. Since the cells of Schwann are missing, repair and replacement of the optic nerve are impossible. The nerve partly functions before birth, pupillary reactions having been observed in six months premature infants.

The optic nerve is not sensitive to pain, nor to physical or electric excitation. Phosphenes and pain resulting from optic nerve section, are due to traction on the retina and to pressure on the ciliary nerves. These phosphenes do not occur in sections of the intracranial portions of the nerve. The nerve carries principally centripetal impulses which travel at the rate of 300 feet per second, and which are generated by the ganglion cells in the retina. Basic

qualities common to all nervous tissues such as the summation and the all or nothing reactions, are also present in the optic nerve. The retina is ten times more sensitive than any photographic emulsion known. Two types of chronaxie are known to exist; (a) those of the photo-motor fibers are four times more rapid than the visual fibers, (b) those of the macular region are more rapid than those of the periphery. Both have been measured by phosphenes produced by electric excitations of known intensities. If the visual cells are solely involved all chronaxies are normal. If the bipolar cells are solely involved, direct excitation will produce abnormal chronaxies. If the ganglionic neurons are involved, only papillary excitation will produce abnormal chronaxies.

All nerve cells are sources of electricity producing two intensities of current; one in the dark and the other in the light. As these waves are similar in form, amplitude, and speed, strong excitations produce a larger number of waves. The latent period of optic nerve waves is 0.1 second. The onset of each wave is brusque and the succession of waves which follow are variable in duration. Different fibers carry different types of messages. Cones are essentially adapted for day vision and color vision; rods for night vision. Recently photochemical substances have been isolated from the cones, each with a different curve of absorption. One substance is sensitive to red, another to yellow, and a third to blue. These substances are not as strong as the visual purple of the rods, but are more rapidly reproduced and are reversible. Thus there are three types of cone fibers; one carrying red impressions, another yellow-green; a third blue.

These are combined in the brain to give the sensation of the color. The visual cortex acts as a huge central telephone exchange which receives and translates these messages. The exact relation of the pupillomotor fibers to the visual fibers is not known. Destruction of the geniculate body and the geniculate route does not modify pupillary mobility, which suggests a possible bifurcation of some fibers before they enter these parts. Anatomically and physiologically this does not seem probable because blindness may occur from optic atrophy with conservation of the photomotor reflex. Pupillomotor fibers apparently do not cross at the chiasm as do the visual fibers because antero-posterior section of the chiasm does not modify the pupillary reactions, direct or consensual. Stimulation of the chiasm and the optic tract however do produce a pupillary contraction. The pupillary fibers apparently occupy the internal border of the optic tract. Pupillomotor fibers carry messages involving pupillary contraction and dilatation, which is important in understanding the Argyll Robertson sign and the Adie syndrome.

The integrity of all nerve fibers depends upon the body of the neuron. The optic nerve has an axone in the ganglion cells.

Intoxications primarily attack different neurons and different fibers. Tobacco poisoning, for example, is accompanied by scotomas which become paracentral on the temporal side and may extend to the blind spot. Since all chronaxies are normal, the process is essentially a destruction of the red-green photochemical substances which eventually affects their cones. These toxic substances are transmitted to the retina from the choriocapillaris. Sec-

ondary temporal disc pallor is therefore due primarily to death of specific cones. In intoxication with barbiturates, alcohol, and lead, the ganglion cells are primarily affected. A secondary optic atrophy follows. Profound ischemia of cells involved in vision, if it lasts fifteen to forty-five minutes, usually results in rapid and often permanent loss of sight because the cells involved never return to normal.

Both centripetal and centrifugal degenerations occur in the optic nerve. After severe injuries slightly anterior to the chiasm several weeks elapse before the papilla becomes pale. The optic nerve is most vulnerable in the optic foramen. Charles A. Bahn.

Mollenbach, C. J. Delayed recovery in retrobulbar neuritis. *Acta Ophth.*, 1943, v. 21, pts. 1-2, pp. 126-132.

Three cases are reported. A woman 53 years of age had a small central scotoma and 6/60 visual acuity, with temporal pallor of the optic disks. Improvement set in 1½ years after the onset of the symptoms, and after 2½ years recovery was complete with vision 6/6 and 6/9 in the right and left eye, respectively. A man 54 years of age began to improve slowly 11 months after the onset of the illness. At the end of two years his vision improved from 6/60 to 6/12, and the relative central scotomata were much smaller in size. The third patient, a man, 31 years of age, had Leber's optic atrophy and after an improvement in visual acuity which began one year from the onset of the disease and lasted six months, visual acuity was again badly impaired, and the scotomata increased in size. (3 visual fields).

Offret, G. Concentric bodies in the sheath of the optic nerve, their significance and clinical interest. *Arch. d'Ophth.*, 1946, v. 6, no. 1, pp. 29-42.

Offret notes that concentric bodies (corpora arenacea) are seen in eyes from patients with various eye diseases, often without optic nerve involvement. The bodies are always found in connection with the arachnoid, generally in the subdural space. Since they are not seen apart from arachnoid cells, the author concludes that they must be formed by this membrane. He examined a large number of optic nerves from embryos, fetuses, infants, adults, and aged persons in longitudinal and transverse sections and found the bodies only in adult and aged eyes. He describes in some detail the morphology and constitution of the bodies and stresses the role of cell nests in their formation. The various stages in the formation of the bodies are described and the tinctorial properties noted. The author found the distribution of the bodies to be of interest. The majority were in contact with the dura, which they penetrated more or less deeply, and there was a concentration in the zone of the central vessels. He notes the similarity of the bodies to those encountered in the normal cerebral meninges and in meningoblastomas. The article is illustrated with twelve drawings.

Phillips Thygeson.

Perera, C. A., and Stout, A. P. Intra-orbital melanosis and intracranial neuroepithelioma of the optic nerve. *Arch. of Ophth.*, 1946, v. 35, June, pp. 678-687.

A two-year-old Armenian girl was observed with glaucoma of the right eye. An iris inclusion operation was done which was followed by recurrent hemorrhages and finally, enucleation.

During the enucleation a ring of pigmented tissue was noted around the optic nerve extending about one inch into the orbit. This tissue was dissected out. Pathologic studies of the eye showed, in addition to the glaucomatous changes, complete detachment of the retina and a dense connective-tissue membrane behind the lens. In the optic nerve behind the globe was seen an unusual pigmented lesion, associated with rounded, hyaline masses and small psammoma bodies. A diagnosis of melanosis of the optic nerve was made. Later the child developed signs of a brain tumor and died. A neuroepithelioma of the right optic nerve, the optic chiasm, and the base of the brain was found. Complete pathologic studies of the involved tissues are reported. The literature dealing with melanotic lesions of the leptomeninges is discussed. (Eight photographs.)

John C. Long.

Rintelen, F. Arteriosclerotic optic atrophy. *Ophthalmologica*, 1946; v. 111, April-May, pp. 285-290.

The author's investigation consisted of the examination of 35 optic nerves from persons between 44 and 48 years of age. They were compared with eight nerves of younger persons with healthy vessels. The pathologic examination showed patches of degenerated nerve fibers with overgrowth or glial tissues and cyst formation caused by partial vascular occlusion, mostly close to the optic disc. The disease is not rare and may be the most frequent type of optic atrophy.

The diagnosis rests chiefly on the exclusion of other causes for the atrophy.

The author distinguishes three forms of arteriosclerotic optic atrophy. The

benign form characteristically affects old persons and manifests itself in the periphery of the nerve as senile capillary necrosis. A malignant form occurs in young people as well and progresses rapidly. Softened plaques appear in the optic nerve especially in the vascular part. Clinically this form may suggest glaucoma without hypertension. A third form results from direct pressure of the sclerotic carotid artery on the optic nerve and is clinically rare.

Alice R. Deutsch.

Rønne, Henning. The inheritance of Leber's disease. *Acta. Ophth.*, 1944, v. 22, pt. 2, pp. 203-213.

The author disagrees with Ruth Lundsgaard's conclusions (Leber's disease, Copenhagen 1944, Gyldendalske Boghandel) as to the type of inheritance of this disease. By an analysis of 12 of Lundsgaard's pedigrees and of 7 referred to by her in the literature Rønne believes to have demonstrated that the inheritance of Leber's disease is cytoplasmic and not autosomal.

Ray K. Daily.

Rucker, C. W. Bitemporal defects in the visual fields resulting from developmental anomalies of the optic disks. *Arch. of Ophth.*, 1946, v. 35, May, pp. 546-554.

One of the most dependable axioms in ophthalmology is that bitemporal hemianopsia indicates a lesion at the optic chiasm. Six cases reported here demonstrate that even to this rule there may be exceptions which can occasionally cause difficulty in diagnosis.

The types of field defects illustrated in these cases have been recognized for many years and are briefly described in two of the current standard textbooks on perimetry.

When it is suspected that a bitem-

poral hemianopic depression is due to anomalous disks rather than to a chiasmal lesion, the way in which the defect behaves at the midline may be diagnostically helpful. If it passes smoothly from the temporal into the nasal field without deflection, it is probably the result of a distortion of structures at the nerve heads. A distinct step at the midline occurs in association with chiasmal lesions.

R. W. Danielson.

Van Bogaert, L., and Van Leeuwen, A. First anatomic and clinical observations on the hereditary familial optic atrophy of Behr. *Bull. Acad. roy. de med. de Belgique*, 1942, v. 7, April, pp. 218-225.

The authors describe their observation of a patient with hereditary optic atrophy. From a pathologic study of the tissues they conclude that in the optic system the second neuron is degenerated in its entirety; the third is almost intact, the visual cortex normal. They do not mention the condition of the first neuron (bipolar cells) or the rods and cones. They found an associated cerebello-spinal degeneration of the Friedreich type. This disease is an essentially degenerative one and the types of Leber and Behr, are variations of the same heredo-familial degenerative process.

VISUAL TRACTS AND CENTERS

Brenta, J. and Danis, P. Bitemporal hemianopsia of traumatic origin. *Ophthalmologica*, 1946, v. 111, Jan., pp. 8-27.

The authors report in detail their observations of a patient with a post-traumatic chiasmal syndrome and thoroughly analyze their findings in the

light of data in the literature. In some cases direct mechanical trauma is the cause of the disturbances of vision and a sagittal tear of the chiasm that sometimes includes neighbouring tissues. In others a secondary process following the injury must be added to the mechanical effect and in a third category the secondary process alone produces the symptoms. It is obvious that the syndrome indicates an injury to the chiasm, but, since its appearance is apparently not dependent upon injury to the chiasm by a fragment of bone, its value in localising the fracture in the middle cerebral fossa is restricted. Its prognostic importance is dependent on the mode of origin. The investigation of visual disturbances must be continued over a long period; their increase may necessitate an operation in the area of the chiasma. (13 figures, references.)

F. Nelson.

Greear, J., and McGavic, J. **Visual disturbances associated with head injuries.** *Arch. of Ophth.*, 1946, v. 35, July, pp. 33-54.

The authors review the literature and report twelve cases of head injury in battle casualties. It was found that correlation of visual-field defects with definitely known sites and types of head injury, the notation of lesions found at operation and the results of roentgenographic examination of the skull offers the best method of studying the cortical representation of various areas of the retina. Cortical representation of the fixation area (macula) is similar to cortical representation of the peripheral portions of the retina. The fixation area is represented at the posterior tip of the occipital lobes, while the peripheral portions of the retina are represented in the cortex at

the anterior end of the calcarine fissure. Similarly, the upper half of the retina is represented in the cortex above the level of the calcarine fissure, while the lower half of the retina is represented below the calcarine fissure. Neither the fixation area (macula) nor the peripheral area of the retina has duplicate areas of representation. (References, 12 illustrations.)

Knapp, P., and Schwarzmann, A. **Contraction in the visual fields caused by a diencephalic lesion.** *Ophthalmologica*, 1946, v. 111, April-May, pp. 270-278.

Concentric contraction of both fields of which the patient is unaware is a new symptom in diseases of the diencephalon. An illustrative clinical history is reported. The patient had the visual disturbance and endocrine and vasomotor changes such as hyperthyroidism, secondary amenorrhea, migraine, fainting spells, and acrocyanosis.

The anatomy and physiology of the diencephalon and the treatment are reviewed. (2 fields, references.)

Alice R. Deutsch.

Knüsel, O. **Demonstration of visual fields in an opticochiasmal arachnoiditis.** *Ophthalmologica*, 1946, April-May, v. 111, p. 298.

The author reports the clinical record of a patient with opticochiasmal arachnoiditis. The patient had headache, impairment of vision, and loss of weight after cranial injury. There was concentric contraction and a ring scotoma in the right eye, and concentric contraction and a central scotoma in the left.

Alice R. Deutsch.

Miranda, A. G. **Binasal hemianopsia.**

Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, June, pp. 472-492.

A case of an infiltrating subcortical glioma of the frontal lobe in a man 33 years of age is reported. The initial symptoms were headache, dizziness, and vomiting, followed rapidly by visual disturbances, bilateral choked discs, and a binasal hemianopsia. The diagnosis was confirmed surgically. The literature on binasal hemianopsia is reviewed, and reference made to Zeeman's publication in *Ophthalmologica* in 1943. The author concludes that binasal hemianopsia is a pathologic entity indicative of a lesion of the optic nerves in their intracranial portion, consecutive to a dilatation of the third ventricle, or to a parachiasmatic lesion. (12 illustrations.) Ray K. Daily.

Schlezinger, N., Alpers, B., and Weiss, B. Suprasellar meningiomas associated with scotomatous field defects. *Arch. of Ophth.*, 1946, v. 35, June, pp. 624-642.

Suprasellar meningiomas are characteristically associated with atrophy of one or both optic nerves and bitemporal hemianopsia. In almost all instances the symptoms are slowly progressive, with prominent visual loss and disabling headache. Not sufficiently well recognized as part of the suprasellar tumor syndrome is the occurrence of sudden visual loss with scotomas in the visual fields, associated with headache. The development of symptoms may be so rapid as to suggest the presence of retrobulbar neuritis.

Four cases of proven suprasellar meningiomas are reported with details of the physical findings, including visual fields. They illustrate the early occurrence of scotomatous field defects. The authors believe that the syndrome

of atrophy of the optic nerve with bitemporal visual field defects should be broadened to include the combination of optic nerve atrophy and expanding scotomatous field defects. In the absence of headaches and of deformities of the sella turcica, this syndrome is sufficient to warrant routinely the performance of complete examination of the spinal fluid and pneumoencephalography.

Since meningiomas are benign tumors and the suprasellar region is accessible to the neurosurgeon, an early diagnosis is desirable. (References, 9 figures.) John C. Long.

EYEBALL AND ORBIT

Giscard, A. Pulsating exophthalmos in pregnancy. *Ann. d'Ocul.*, 1946, v. 179, no. 2, pp. 108-111.

A woman, 21 years of age, in the sixth month of pregnancy noticed a sharp head pain during defecation. Prominence of the eye was observed together with a pulsation synchronous with the pulse. There was also dilatation of the periorbital veins and bulbar conjunctival vessels. Ligation of the common carotid was refused. During the fourth month of a subsequent pregnancy intracranial pulsation became more intense. A basal hysterectomy was performed under spinal anesthesia, and a vigorous baby of seven pounds was born. Fifteen months later the ocular symptoms were unchanged.

Charles A. Bahn.

Gruyton, Jack. Decompression of the orbit. *Surgery*, 1946, v. 19, June, p. 790.

Gruyton reviews the literature on the various surgical approaches to the orbit for its decompression. He compares the advantages and disadvan-

tages of the intracranial, sinus, and lateral approaches. He describes a technique for lateral orbital decompression which is a modification of the Shugrue operation described in Spaeth's textbook. He reports five patients operated on by this technique, two of them bilateral, with a reduction of the exophthalmus of 3 to 7 mm. He feels that this operation is the safest, has least danger of postoperative infection, and avoids the postoperative pulsation which often follows. (Bibliography.)

John B. Hitz.

Hanbery, J. W. **Orbital tumors.** Stanford Med. Bull., 1946, v. 4, May, pp. 52-62.

The most constant sign of intra-orbital tumors is unilateral exophthalmos. In the order of frequency of occurrence the growths are: blood vessel tumors, pseudotumors, meningiomas, osteomas, neurogenic tumors, sarcomas, dermoid and epidermoid cysts, lacrimal gland tumors, and xanthomas. The temporal transconjunctival, the lateral Krönlein, and the Dandy transfrontal approach are described. Twelve cases are reported. (3 tables and six figures.)

I. E. Gaynon.

Marcks, K., and Zugsmith, G. **Plastic repair of deformities of the socket and minor defects about the orbit.** Arch. of Ophth., 1946, v. 35, July, pp. 55-69.

As a preliminary to discussion of plastic repair the authors state that there are essentially four types of sockets, depending on the method by which the eye is removed. The sockets formed by enucleation of the globe without an implant, and those formed by enucleation of the globe and implantation of a sphere, are inferior to those formed by evisceration of the globe

contents, removal of the cornea, closure of the sclera without an implant and coverage with conjunctiva. With the latter the motility and appearance of the prosthesis, are much better. The socket formed by evisceration of the ocular contents with an implanted sphere placed in the scleral sac, followed by closure of the sclera and conjunctiva undoubtedly gave the best results.

Associated with the alteration in function in the socket, various changes occur in the conjunctiva and the changes that occur after each type of removal are delineated. A discussion follows of the technique used in complete lining of the socket with skin, absence of conjunctiva, absence of inferior cul-de-sac, absence of cul-de-sac due to redundancy of mucous membrane, skin-mucous membrane combination, complications existing in socket repair, and atony of the lower lid.

Patients are going to be more and more critical of results, and surgery will need to be of the best. (7 illustrations.)

Orzalesi, Francesco. **Localized metastatic scleritis with exudative detachment of the retina.** Riv. di Oftalm., 1946, v. 1, Feb., pp. 73-84.

A woman, aged 47 years, developed a phlegmon of her left orbit with tenonitis, scleritis, iritis, and almost complete retinal detachment during the course of a severe furunculosis. Vision was reduced to the ability to count fingers excentrically at 50 centimeters. Sulfathiazole and autogenous vaccine, was used for treatment which was followed by complete reattachment of the detachment in five months and a visual acuity of 10/10. (References.)

K. W. Ascher.

Taylor, W. O. G. The nervous nasalis complex of Charlin. *Proc. Roy. Soc. Med.*, 1946, v. 39, March, p. 254.

A young African soldier admitted to an army hospital had suffered pain in his right eye for eight days. Blepharospasm and limbal injection were present. A preliminary diagnosis of iritis was made. Cultures, smears, and blood studies were all negative. Atropine and heat were prescribed.

Four days later beads of sweat gathered at the right side of the tip of his nose which reappeared within a few minutes after they were wiped away. Many fine postcorneal precipitates were seen on slitlamp examination.

Radiant heat therapy was of no avail. The eye became worse and the patient suffered reflex pain in the teeth and the head on the same side. Nerve block was performed by injections of 2 cc. of 3 percent novutox deep in the medial wall of the middle of the orbit. Early relief and complete cure occurred within ten days.

The author differentiates this syndrome of the nasal nerve from that of the pterygo-palatine ganglion.

EYELIDS AND LACRIMAL APPARATUS

Barrenechea, S., and Contardo R. Dacryocystorhinostomy (Arruga's technique). *Arch. Chilenos de Oft.*, 1945, v. 2, Nov.-Dec., pp. 14-18.

Using the technique of Arruga, the authors operated on 43 cases, with 35 completely successful, 4 incompletely successful, and 4 failures. They conclude that this operation should be performed by preference in those young individuals in whom it is desired to preserve the lacrimal drainage channels

with avoidance of radical operations such as extirpation or destruction of the lacrimal sac. (2 statistical tables, 2 X-ray plates, references.)

W. H. Crisp.

Ferrié, J. Davis' grafts in reconstructive facial surgery. *Ophthalmologica*, 1945, v. 110, Nov.-Dec., pp. 292-299.

After surveying the various methods of autoplasty used in corrective face surgery, the author rejects some as unesthetic, and others as unreliable or incomplete. He favors the Davis method, for severe burns and for the correction of cicatricial ectropion of the upper eyelid. It is a simple method and gives satisfactory esthetic results. (3 photographs, references.)

F. Nelson.

McArthur, G. A. D. Some notes on West's operation. *Med. Jour. Australia*, 1946, v. 1, April 13, p. 508.

In 38 patients 42 sac operations were performed. Thirty-one patients were relieved and 35 operations were successful. Among the seven failures the eyes in two, previously constantly moist, were now almost constantly dry. The others were improved markedly.

The author feels that this operation should be performed by the rhinologist. General anaesthesia is required and where septal resection is necessary nasal packing for 24 hours is indicated. He feels that this operation is gradually supplanting sac removal except where cataract extraction is necessary. The West operation is considered the easiest in sacs with chronic infection where a good result can usually be predicted.

Francis M. Crage.

Mellick, A. Case of secondary

oblique facial cleft. *Brit. Jour. Ophth.*, 1946, v. 30, April, pp. 221-224.

An unusual case of partial oblique facial cleft in a soldier is presented. The defect consisted of a bridge of skin from the site of the upper canaliculus to the plica semilunars. The lower canaliculus was normal and patent. The defect is ascribed to an adhesion or pressure from an amniotic band. (4 illustrations.)

Morris Kaplan.

Pokhissoff, N. Treatment of eversion of the lacrimal puncta. *Ann. d'Ocul.*, 1946, v. 179, no. 1, pp. 41-49.

After a review of numerous operations, the following method is discussed in detail. After anesthesia of the inferior lid and its conjunctival lining two sutures are placed through the entire thickness of the lid at the internal angle. The lid is supported by a Jaeger lidplate. With a scalpel the conjunctiva is dissected under the lacrimal puncta to form a triangular flap with its base up. A second triangle is made, the base of which is the prolongation of the internal side of the first triangle. The base of this triangle is about 3 mm. long and the flap is situated 2 mm. from the lid border. These flaps form two Ls which are united; the obtuse angle interiorly, the acute angle exteriorly. The second flap is excised with scissors and the margins united with four or five sutures. The first reunites the angles of the two Ls, and the other sutures unite the margins of the horizontal wound. The sutures are removed three or four days later. The dimensions of the flap can be varied.

Six illustrative cases are described. Twenty-five operations were performed by the author; five binocular and twenty monocular. All patients

were observed at least ten months. (21 references.)

Charles A. Bahn.

deRoeth, Andrew. Penicillin in hordeolosis. *Northwest Med.*, 1946, v. 45, Sept., pp. 658-660.

Applications of penicillin in the form of ointment is advocated in recurring styes. Attention is drawn to the possibility of dermatitis following prolonged use. Applications of 2,000 units per c.c. are made for times a day for eight to fourteen days.

A. G. Wilde.

Stein, S. Treatment of chronic blepharoconjunctivitis with penicillin ointment. *Arch. of Ophth.*, 1946, v. 35, June, pp. 655-661.

The history, method of assay, and bacterial sensitivity of penicillin are reviewed. An ophthalmic ointment containing 100,000 Oxford units of penicillin in 7 grams of base was prepared with wool fat, petrolatum and water. This ointment, for all practical purposes, was stable at room temperature for one month.

Twenty-five patients with chronic blepharoconjunctivitis were treated with this ointment. A single daily dose containing 700 to 800 Oxford units was employed. All but two responded favorably to this treatment. The penicillin ointment has a decided advantage over drugs formerly used in the treatment of chronic blepharoconjunctivitis. There was no evidence of an allergic reaction to penicillin in the series of 25 cases. (References.)

John C. Long.

Ural, Z. Cases of Marcus Gunn phenomenon. *Oto-Nöro-Oft.*, 1946, v. 1, no. 2, p. 69.

Two cases of Marcus Gunn phenomenon observed in young men are reported. Both had ptosis of the left upper

lid. The author believes that this is significant.

F. H. Haessler.

TUMORS

Barraquer, M. B. A plexiform neuroma of the caruncle and the ciliary border. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, April, pp. 245-251.

A case of this rare tumor situated bilaterally on the caruncles, and ciliary border of the lower lids is reported. The diagnosis was made microscopically. A general examination of the 52-year-old woman revealed no other hereditary or congenital lesions. (7 illustrations.)

Ray K. Daily.

Cortez-Herman. Plasmoma of the conjunctiva. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, April, pp. 238-244.

A mass in the lid of a 21-year-old woman was found microscopically to be a plasmoma. It was successfully destroyed by diathermy. (6 illustrations.)

Ray K. Daily.

16

INJURIES

Aiello, G. Trinitrotoluene intoxication and ocular affections. *Ann. di Ottal. e Clin. Ocul.*, 1946, v. 73, Jan., pp. 17-21.

The author presents and discusses the case of a 23-year-old female munitions worker presumably suffering from trinitrotoluene poisoning, who showed numerous small punctate and flame-shaped hemorrhages along the retinal vessels, low-grade secondary papillitis, a stellate figure in the macula, and eventually a large vitreous hemorrhage. No underlying systemic disease could be found (blood pressure was normal, examination of the urine was

essentially negative, and examination and tests for tuberculosis were also negative), but the possibility of the concomitant action of other toxic substances was admitted.

Harry K. Messenger.

Dufour, R. The X-ray localization of intraocular foreign bodies. *Ophthalmologica*, 1946, v. 111, April-May, pp. 310-314.

The author uses a 9-mm. metallic ring and a new graph which he superimposes on anteroposterior and profile X-ray exposures of the eye. The foreign body is exactly localized with compass and rule. Alice R. Deutsch.

Grana, P. C. Conjunctivitis and dermatitis due to "Beach apple." *Arch. of Ophth.*, 1946, v. 35, April, pp. 421-422.

Thirteen casualties were observed in troops stationed in Panama from the use of a poisonous plant, *Hippomane manchinella*, in camouflage. Within two hours of contact with the shrub excruciating pain developed in the eyes accompanied by excessive tearing, injection of the conjunctiva, and slight chemosis. The skin of the face showed a diffuse, patchy erythema and swelling. The use of dilute boric acid solution for the eyes and dilute sodium bicarbonate solution for the skin proved effective. The average stay in the hospital was three days, and no complications occurred.

John C. Long.

Hughes, W. F. Alkali burns of the eye. *Arch. of Ophth.*, 1946, v. 35, April, pp. 423-449.

This is a detailed review of the literature and summary of the present knowledge on this subject. Alkali burns are progressive in type, and serious late

complications frequently develop after little evidence of early injury. The severity of the lesion is less dependent upon the character of the cation than on the concentration of the alkali, the pH of the solution, and the duration of the exposure. In contrast to acid burns, the mucoid content of the cornea decreases.

Treatment effective for mild and moderately severe alkali burns consists of immediate irrigation with copious amounts of water or any bland solution, a thorough search and removal of any residual particles of alkali hidden within the conjunctival cul-de-sacs, followed by instillations of buffer solution (pH 4.5), instillation of mydriatics, use of 10 percent neutral ammonium tartrate (or lactate) after lime burns, instillations of sulfonamide or penicillin ointments to prevent secondary infection, and prevention of symblepharon. Early and repeated corneal paracentesis resulted in exceptionally good results in some reported cases. The early excision of necrotic conjunctival and episcleral tissue and its replacement with mucous membrane or conjunctival grafts has been employed in severe burns. Analysis of these reported cases does not reveal any striking benefit attributable to such a procedure. John C. Long.

Kutscher, C. F. **Ocular effects of radiant energy.** *Indus. Med.*, 1946, v. 15, May, p. 311.

After a preliminary discussion of the nature of radiant energy, its absorption by the tissues of the eye is discussed.

Infrared radiations longer than 30,000 Angstrom units are completely absorbed by the cornea; below this level corneal transmission increases slowly, and at 11,000 A.U., 96 percent

of the radiation is transmitted. The lens absorbs infrared between 18,000 and 10,000 A.U. The iris absorbs all infrared, translating this energy into heat which is dissipated either by the iris vessels, or by raising the temperature of the aqueous. Very little infrared radiation reaches the retina, and a thermal burn on this basis is very unusual.

All visible light (7,800 to 3,900 A.U.) is transmitted to the retina, where an excessive dose may produce a thermal burn. Ultraviolet light is absorbed by the lens, beginning at 3,800 A.U. Radiation the wavelength of which is 3,200 A.U. is completely absorbed. Below this level the cornea absorbs ultraviolet.

Only those radiations which are absorbed will produce biologic effects in tissues. Ultraviolet rays cause abiotic, or destructive effects after a latent period of some hours; infrared produces immediate thermal injury.

Corneal burns from infrared rays are uncommon, but show prompt diffuse opacification. More common is the so-called "glass-blowers" cataract, that appears in the posterior axial part of the lens after prolonged exposure to infrared (many years). Ultraviolet more frequently causes painful corneal injury, followed by fairly rapid recovery without residual damage.

Gamma rays produce cataract after several years' interval. Lens opacities have been observed after exposure to lighting or electric currents.

Treatment of these radiant energy injuries is discussed briefly.

Benjamin Milder.

Somerville-Large, L. B. **An operation for posterior route extraction of intra-ocular foreign bodies.** *Brit. Jour.*

Ophth., 1946, v. 30, April, pp. 208-213.

A method for the extraction of magnetic foreign bodies through the posterior route is described. Its essential characteristic lies in the use of a 1.5 mm. trephine opening through the sclera nearest the foreign body. The disc is dissected from the choroid which is punctured by diathermy or actual cautery. A point of the giant magnet is inserted. The conjunctiva is sutured over the trephine hole. No vitreous leakage or other complications occurred. The operation was carried out 24 times. (3 illustrations.)

Morris Kaplan.

Hertzberg, R. **Quinine amaurosis, report of case.** Med. Jour. Australia, 1946, v. 2, July 20, pp. 92-93.

The patient noted that after taking 50 grains of quinine sulfate, his vision became blurred and on the third day he was unable to see at all. Atabrine was substituted for quinine and the following day, vision began to return. The pupils were dilated and immobile, there was edema of the macula in each eye, and the fields were normal. Two days later the discs became pale and the arteries attenuated. After two weeks visual acuity was 6/6 and the pupillary reactions normal, although the vessels were still attenuated and the discs pale.

SYSTEMIC DISEASES AND PARASITES

Argañaraz, Raul. **Ocular manifestations of "sacred disease."** Arch. de Oft. de Buenos Aires, 1943, v. 18, Nov., p. 546.

The author studied the ocular findings in seven cases of epilepsy. Most of the patients presented clinical evidence of other neurologic lesions. The ocular

findings consisted of enlargement of the blind spot, which was invariably found, constriction of the visual fields, congestion of the papilla, and optic neuritis or atrophy. The author points out that textbooks of ophthalmology fail to record ocular findings of significance in epilepsy and stresses the importance of the ophthalmologic examinations in the diagnosis of this disease. (Visual field charts.)

Plinio Montalván.

Barriere, L. A. **Orbital miasis.** Arch. de Oft. de Buenos Aires, 1943, v. 18, Nov., p. 585.

A case of orbital miasis in a 70-year-old man is reported. The lesion consisted of an extensive ulcerative process involving the lower lid and soft tissues of the cheek and penetrating deep into the orbital cavity. The globe was destroyed by panophthalmitis. After the removal of the larvae the lesions healed quickly leaving considerable granulation tissue. The life cycle of the larva and the mechanism of infestation are briefly discussed. (Illustrations and bibliography.)

Plinio Montalván.

Cullom, M. M. **Role of sinusitis in eye pathology.** Laryngoscope, 1946, v. 56, April, p. 164-179.

The author presents detailed case histories of 16 patients, each of whom showed unequivocal improvement of the ocular disease following radical sinus surgery. In each instance the sinusitis was sufficiently pronounced that it constituted a justifiable indication for surgical intervention. The eye diseases which improved included six ulcerations of the cornea, two retinochoroiditis, and four which were diagnosed as toxic amblyopia.

Benjamin Milder.

Knapp, Paul. Alopecia of one eyebrow. *Ophthalmologica*, 1946, v. 3, Feb.-March, p. 67.

A girl, 27 years of age, lost practically all the hairs of the left eyebrow after severe recurrent attacks of a neuralgia in the left side of her forehead. A normal condition was only restored after more than a year. A trophic disturbance, probably caused by an affection of the left ethmoid, might have been the reason for this unusual occurrence.

Alice R. Deutsch.

Pacheco-Luna, R. Notes on oncocerciasis in Guatemala. *Brit. Jour Ophth.*, 1946, v. 30, April, pp. 234-237.

A brief review of the picture of oncocerciasis is given. It is very common in Guatemala where it is estimated that 20,000 people are infected. Ocular manifestations are present in 30 percent and 2 percent are blind. The adult filaria are found in subcutaneous nodules about head and eyes. The microfilaria migrate from these tumors in the lymph channels. They are very easily seen in the corneal stroma, conjunctiva, and vitreous, and swim actively in the aqueous. The most distressing early symptom is photophobia which is followed by a punctate keratitis. Gradual sclerosis and atrophy follow. These signs and symptoms may persist for many years. The author observed one for 25 years. There is no treatment although extirpation of the subcutaneous tumors retards the spread of the disease.

Morris Kaplan.

Puig Solanes, Magin. Present condition of the clinical ocular problem of onchocercosis. Reprint from *Rev. Méd. del Hosp. Gen.*, 1946, v. 8, Feb., pp. 339-414.

The paper was presented to the Pan-American Congress of Ophthalmology at Montevideo in November, 1945. To some extent it repeats the material contained in the paper entitled "Onchocercosis in the State of Chiapas" (see below), utilizing 11 illustrations and over two pages of references, mostly Ibero-American.

W. H. Crisp.

Puig Solanes, M., Fontes, A., and Quiroz, J. A. Onchocercosis in the State of Chiapas. Reprint from *Rev. Salubridad y Asistencia (Mexico)*, 1945, July-Aug., pp. 69-96.

This paper summarizes the results of a clinical investigation in the onchocercosis zone of the State of Chiapas. A number of statistical details are given, together with 19 black and white photographic illustrations. The work is completed by a large and comprehensive statistical table.

W. H. Crisp.

Sala, G. Hepatolenticular degeneration (Wilson's disease) and ocular signs. *Riv. di Oftalm.*, 1946, v. 1, Feb., pp. 124-139.

A girl 13 years of age, with typical Wilson's disease, had bilateral Kayser-Fleischer corneal rings and very faint opacities in anterior polar region of the lenses. The latter were yellowish, and under the corneal microscope minute radial extensions of the same color were seen. The opacities were immediately beneath the lens capsule. Whereas Kayser and Fleischer described the corneal rings connected with "pseudosclerosis" in 1902 and 1903 respectively, the first case of Kayser-Fleischer's corneal ring associated with sunflower cataract was reported by Siemerling and Oloff, in 1922. The lens opacities, that are noted in patients with Wilson's disease, are very similar to those en-

countered in eyes with chalcosis. The diagnostic importance of both the Kayser-Fleischer ring and the sunflower-like lens opacity for the recognition of Wilson's disease is stressed, and the opinions as to the chemical constitution of these opacities are discussed. (References.)

K. W. Ascher.

Schmid, A. E. *Dysmorpho-dystrophia mesodermalis congenita*. *Ophthalmologica*, 1946, v. 111, Jan., pp. 28-60.

The author reports his investigation of a patient with this hereditary anomaly, her family tree, and a thorough analysis of the theoretical implications in the light of discussions of the subject in the literature. The patient, a girl, 17 years of age, had strikingly short fingers, hands, toes, and feet. In early childhood she had bilateral inguinal hernia, vaginal prolapse, scoliosis, and defective mobility of her joints. In each eye the lens was small, spherical, and ectopic. In the right eye it was luxated into the anterior chamber and in the left eye into the vitreous. In each eye there was atrophy of the iris with synechia and an anomaly of the optic disc. The patient is compared with a classmate who had arachnodactyly. Both conditions are inherited according to the same pattern and differ only in the length and width of body and extremities. Incomplete forms of both anomalies are more common than the fully developed symptom complex. The author suggests that the Marfan type be called dolichomorphy and the Marchesani type brachymorphy. Etiologically the condition is assumed to be a mesodermal dystrophy. (6 photographs, 7 drawings, 1 family tree, references.)

F. Nelson.

Tinelli, Giuseppe. The syndrome of Laurence-Moon-Bardet-Biedl. *Boll. d'Ocul.*, 1944, v. 23, Oct.-Dec., pp. 257-280.

A young man, 18 years of age, is described who had adiposo-genital dystrophy, esodactily of the feet, mental deficiency, hemeralopia, greatly reduced vision, convergent strabismus, vertical nystagmus, retinitis pigmentosa without pigment, and secondary optic atrophy. Metabolic investigations revealed that the diencephalic-hypophyseal system was affected. He was a son of consanguineous parents and one of his two brothers was mentally deficient. All similar cases reported in the literature are chronologically tabulated. The most important pathogenetic theories in this field are discussed. (Bibliography.)

Melchior Lombardo.

18

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Blake, E. M. *Prevention of blindness*. *Conn. State Med. Jour.*, 1946, v. 10, May, Pp. 379-382.

The prevention of blindness is not a problem for the ophthalmologist only, but for the medical profession as a whole.

The incidence of ophthalmia neonatorum should be reduced to almost zero by modern preventive measures, plus chemotherapy and antibiotics.

With premarital blood tests and treatment with penicillin, blindness in childhood from syphilis should almost never occur.

During childhood and throughout adolescence the principal cause of blindness is accident. Accidents can only be prevented by education of

parents and children, and the continuous reiteration of "don'ts" with explanations of the reason for the "don'ts."

The greatest loss of vision, while not leading to blindness, but to great reduction in sight is in strabismus. Early ophthalmologic examination of all children, and treatment for strabismus where necessary is indicated.

Chronic simple glaucoma is the most important single cause of loss of sight today. The ophthalmologist should take the tension of the eye with a tonometer in all patients over 45 years of age.

There is not much hope of prevention of cataract as it is one of the manifestations of tissue senility.

In industrial medicine preemployment ophthalmologic examination is of importance both to employer and employee. The wearing of protective glasses in industry where the need is indicated, reduces the risk of accidents.

Theodore M. Shapira.

Galton, E. M. G. **Ocular decompensation.** *Brit. Jour. Ophth.*, 1946, v. 30, April, pp. 232-234.

The author compares ocular symptomatology with cardiac and finds them closely similar. In examining huge numbers of men in the armed services, it was seen that eyes which had previously given no difficulty suddenly caused much discomfort. Since the eyes had not changed anatomically, it was concluded that the neuromuscular system could no longer cope with the new mental and physical load and therefore became decompensated. Sometimes the mere prescribing of lenses aided, but most often the patient had to be treated as a complete medical entity. A plea is made for a continuation of this broad approach to ophthalmic problems.

Morris Kaplan.

Pereira Gomes. **Study of the vision of drivers of vehicles.** Reprint of paper presented before the fifth Congresso Brasileiro de Oftalmologia, 1946, June, 18 pp.

The author presents a partial review of the history of the subject, particularly as concerns the national traffic code in Brazil. The influence of monocular vision is considered as well as details relating to the light sense, dark adaptation, dazzling, hemeralopia, visual field, and tubular vision. Color sense is also discussed. The author concludes by making certain recommendations for amendment of the traffic code in Brazil, in relation to the vision of candidates for appointment in the capacity referred to. (References.)

W. H. Crisp.

Scalinci, Noè. **The Italian contribution to the earliest knowledge of the structure and function of the retina.** *Ann. di Ottal. e Clin. Ocul.*, 1946, v. 73, Jan., pp. 58-59.

Fontana was the first to recognize fibers and cells in the retina, and, what is more important, to perceive that these elements are identical with those of cerebral nervous tissue. It was therefore not Langenbeck (1836) who first noted this identity, but Fontana about sixty years earlier. To Pacini (1845) belongs the priority for giving an approximately exact description of the minute structure of the retina. Golgi's chrome-silver technique of staining (1872-75) led to a more precise knowledge of the finer interrelations of the various layers, and to Tartuferi (1888) belongs the credit for introducing the new era in retinal histology.

The work of other Italians who also pioneered in this field receives brief mention. Harry K. Messenger.

Tisher, P. W. Opportunity for prevention of blindness in industry. Connecticut, M. J. 1946 v. 10, May, p. 382-383.

The losses in production and the human misery which result from industrial eye accidents, of which 90 percent are preventable, may be lessened by pursuing, for each factory, a blindness-preventing program which includes these features: enforced protective glasses; protective shields on machines; proper lighting; cleanliness; eye examinations; and job analysis.

Such a program will result in benefits to the manufacturers, as well as to the workers. Benjamin Milder.

19

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Alexander, G. F. The elastic tissue within the eye. Trans. Ophth. Soc. U. Kingdom, 1944, v. 64, pp. 195-198.

The author states that Descemet's membrane splits into a number of sheets or lamellae which are inserted into the tip of the scleral spur. These lamellae with subjacent corneal lamellae constitute the pectinate ligament. They are non-distensible. The contraction of the radial fibres of the ciliary muscle pulls the choroid forward. The arrangement of the opening of the pectinate ligament produces a valve-like action, allowing the aqueous to percolate into the canal of Schlemm, but preventing any flow of blood into the anterior chamber during venous congestion.

He describes experiments which indicate that there is a definite hyaline membrane of the vitreous and that it is split into two layers. The anterior extends into the zonule of Zinn and the posterior forms the patellar layer. Be-

tween these two layers the canal of Petit is filled with aqueous.

Beulah Cushman.

Minton, J. Ophthalmic experiences in the east. Trans. Ophth. Soc. U. Kingdom, 1944, v. 64, pp. 199-209.

The author describes epidemic ophthalmias as seen in Iraq, Egypt, Palestine, India and Ceylon. The carriers of infection such as flies, dust, and sand and the lowered resistance of the children during the summer months seem to be factors in the development of the epidemics. Trachoma was prevalent and usually followed the epidemic ophthalmias. Syphilis was extremely common but interstitial keratitis was rarely seen. Cataract and glaucoma were found no oftener than in Europe but occurred at an earlier age.

The British troops had few infections, the Indian troops showed a much greater morbidity. The quiescent trachoma so frequently present in the Indian troops might account for some of the infections.

Sulfanilamide ointment was of great value in the treatment of trachoma and in the different types of conjunctivitis.

Beulah Cushman.

Offret, G. A review of modern studies concerning the physiology and psychophysiology of the parietal and occipital lobes of the brain. Arch. d'Opht., 1946, v. 6, no. 2, pp. 145-172.

In this long article Offret gives a comprehensive review of the anatomy and functions of the parietal and occipital lobes. The many ophthalmologic aspects of the subject considered include anomalies of spatial orientation, reading, writing, color vision, and stereoscopic vision. Discussion of these subjects is preceded by a summary of

modern anatomical knowledge in which numerous references to current literature are made although the author has not provided a bibliography. This valuable article does not lend itself to review but should be read in its entirety.

Phillips Thygeson.

Swan, Charles, and Tostevin, A. L. Congenital abnormalities in infants during pregnancy, with special reference to rubella. *Med. Jour. Australia*, 1946, v. 1, May 11, pp. 645-659.

All important data are presented in tabular form and an analysis is presented in the text. In this investigation 56 infants and two fetuses were examined; 46 of them were found to have congenital malformations. In 40 instances, the mothers had rubella; 36 of the infants had congenital defects which with few exceptions were more or less complete reproductions of the syndrome that consists of cataract, deafmutism, heart disease, and microcephaly. In two instances in which rubella was contracted less than two weeks before conception, the infants were normal. In the remaining 16 in-

stances the mothers were ill during pregnancy with morbilli, mumps, varicella, herpes zoster, and scarlatina, and nine of the infants were abnormal.

The development of defects is elucidated on the basis of Stockards experimental studies of eggs of the minnow. The type of abnormality is determined by the particular developmental moment at which the noxa acts. Fetal tissues are susceptible to injury by virus infections and those Anlagen which are in a stage of rapid growth are most vulnerable. It has been stated that if maternal infection occurs in the first six weeks of pregnancy, fetal injury will be widespread. After eight weeks the eyes, heart, and semicircular canals may escape, but the cochlea is still vulnerable. After the third month damage to the fetus is rare. In the light of the data presented by Swan and Tostevin, this view must be modified. There must be other factors at work in determining whether a particular primordium is affected even if it is rapidly proliferating, and has developmental "precedence" over the other centers of growth. I. C. Gaynon.

NEWS ITEMS

Dr. Edward Francis Ritter, Jr., Chicago, Illinois, killed in action in the Asiatic area, October 24, 1944, aged 35 years.

Dr. Theodore Lasater Terry, Boston, Massachusetts, died September 28, 1946, aged 47 years.

MISCELLANEOUS

HEED OPHTHALMIC FOUNDATION

The Heed Ophthalmic Foundation is now offering a limited number of fellowships for advanced training in ophthalmology. Only those who have completed a minimum of two years' specialized study in ophthalmology are eligible. United States citizenship is required.

For further details, refer to an editorial appearing on page 79 of this Journal and in the current *Transactions of the American Academy of Ophthalmology and Otolaryngology*.

Application blanks and additional information may be obtained from the Secretary of the Board of Directors, Dr. M. Hayward Post, 520 Metropolitan Building, 508 North Grand Boulevard, St. Louis 3, Missouri.

FRANCIS I. PROCTOR LABORATORY

The Division of Ophthalmology of the University of California announces the establishment of the Francis I. Proctor Laboratory for Ophthalmic Research. A sum of over \$500,000 from the estate of Dr. Proctor was set aside and given by Mrs. Proctor for this purpose. In addition, as previously announced, Mrs. Proctor has donated a sum of \$20,000 for the establishment of the yearly Francis I. Proctor Lecture on Ophthalmology to be given at the University of California.

Mrs. Berthold Guggenheim has guaranteed a sum of \$65,000 for the construction of a laboratory of 3,000 square feet in the new science building which is to be constructed on the medical school campus as soon as building again becomes feasible. In the interim the laboratory is being housed in temporary quarters.

Dr. Michael Hogan has been appointed director of the Proctor Laboratory.

The plans call for research in the various branches of ophthalmology as soon as facilities are available. In the development of the laboratory, the director and the staff will be aided by the advice and experience of Dr. Phillips Thygeson, who is now a member of the visiting staff.

EYE BANK APPOINTMENTS

The Board of Directors of The Eye Bank for Sight Restoration, Inc., announces the following scholarship and fellowship awards and appointments:

Dr. Herbert M. Katzin, New York, has been put in charge of the Laboratory for Ophthalmic Research of The Eye Bank for Sight Restoration, Inc.

Dr. Frank Constantine has been granted a Fellowship to pursue studies in relation to corneal vascularization.

Dr. Arnold Forest of the Army Institute of Pathology, Washington, D.C., has been granted a Fellowship for training in Ophthalmic Pathology with special emphasis on corneal pathology.

Dr. Milo H. Fritz of New York has been granted a Fellowship to continue studies in vitreous replacement and vitreous transplants.

RESEARCH PROGRAM OF COMMITTEE ON VETERANS' MEDICAL PROBLEMS

At a conference suggested by the Surgeon General, U. S. Army, and attended by representatives of the Chief Medical Director, Veterans Administration, and of the Surgeons General of the U. S. Army, Navy, and Public Health Service, the National Research Council was asked to explore the value and feasibility of a long-term program of follow-up study and clinical research. The report of this investigation was approved by the above agencies and at the request of the Chief Medical Director, Veterans Administration, the National Research Council has appointed a Committee on Veterans' Medical Problems.

The purpose of the Committee is to plan and carry out a medical research program utilizing the wealth of material accumulated during World War II so that the care of patients, the investigation of disease, and the improvement of medical practice and education may be advanced. Medical records of service personnel will be available to accredited representatives of the National Research Council when working on studies approved by the Army, Navy, or Veterans Administration.

The program, dealing with medical problems of veterans and of the armed forces, will include projects of three types: (1) clinical follow-up studies; (2) original investigations which may be carried out in Veterans Administration hospitals or other institutions; and (3) statistical studies on mortality and duration of disability.

The Committee will consider proposals for studies originating from the Veterans Administration, the U. S. Army, Navy, Public Health Service, National Research Council, universities, or other workers. Proposals will be referred to advisory committees of the National Research Council for detailed analysis, after which they will be evaluated by the Committee on Veterans' Medical Problems. Carefully established criteria will be followed, emphasis being placed upon significant long-term research or shorter problems which fit well into the Committee's overall program. The present program is financed by contract with the Veterans Administration. It is hoped that funds will be available for grants in the spring of 1947.

The Committee will attempt to evaluate and assist medical studies of direct or collateral importance to veterans. At the request of the Veterans Administration, it will analyze all proposals for medical research submitted to that agency, whether or not financial support under the Committee's program is needed. In the case of medical officers of the Veterans Administration, Army, or Navy, application forms may be obtained and returned through the appropriate channels. Other agencies or individuals may obtain the forms from, and submit them directly to the Committee on Veterans' Medical Problems, Division of Medical Sciences, National Research Council, 2101 Constitution Avenue, Washington 25, D.C.

After approval of a project, the Committee Office at the above address will offer, when requested, such special services as it is able to render. These will include facilities for statistical planning, aid in securing medical records and preparing rosters, assistance in locating veterans for follow-up studies, and help in analysis of the results obtained.

(Editor's Note. Ophthalmic ex-medical officers have in many instances kept careful records of the patients whom they saw during their military service, and the above plan offers these ex-medical officers an opportunity to carry out what may well be exceedingly valuable clinical follow-up studies on these patients. You are urged to write to Dr. John C. Ransmeier, Medical Executive, Division of Medical Sciences, National Research Council, 2101 Constitution Avenue, Washington 25, D.C., and send him your lists containing the names of individuals who passed through your hands and the kind of diseases or injuries involved.)

GLAUCOMA PRIZE OFFERED

The National Society for the Prevention of Blindness announces that papers submitted for the glaucoma prize of \$500 offered in 1944 did not conform to the criteria set up by the ophthalmic committee selected to award the prize. Therefore, the prize is again offered for the most valuable original paper adding to existing knowledge about the diagnosis of early glaucoma or to the medical treatment of non-congestive glaucoma. The criteria may be obtained by writing to the National Society for the Prevention of Blindness, 1790 Broadway, New York 19, New York.

Papers may be presented by any practicing ophthalmologist of the Western Hemisphere and may be written in English, French, German, Italian, Spanish, or Portuguese. Those written in any of the last four languages should be accompanied by a summary in English. Closing date for receipt of papers is December, 1947.

The award will be made by the Society with the guidance of an ophthalmic committee composed of Drs. John N. Evans, chairman; Frank C. Keil, Daniel B. Kirby, John M. McLean, R. Townley Paton, Algernon B. Reese, Bernard Samuels, Kaufman Schlivek, Willis S. Knighton, Manuel Uribe Tróncoso, and David H. Webster.

SOCIETIES

On November 19, 1946, the New England Ophthalmological Society participated in the program of the annual meeting of the Massachusetts Eye and Ear Alumni Association. The program included: Morning Session—Surgical Clinic conducted by the Eye Staff of the hospital; Afternoon Session—Prof. W. J. B. Riddell, Glasgow, Scotland, delivered the Howe Lecture. His subject was, "Heredity and Variation in Clinical Ophthalmology."

At the evening session—the 372nd regular meeting of the New England Society—Dr. Howard F. Hill presided. Elek J. Ludvigh, Ph.D., of the Howe Laboratory of Ophthalmology, presented a paper on "Visual Acuity Tested with Moving Objects." Prof. W. J. B. Riddell spoke on "Ophthalmological Education."

The second day's meeting opened with a Surgical Clinic. Dr. Frederick H. Verhoeff presided at the afternoon session. The program included:

"Di-isopropyl Fluorophosphate in Glaucoma." Edwin B. Dunphy, M.D.

"Aniseikonia." John P. MacNie, M.D.

"Conjugate Deviation of the Eyes on Forced Closure of the Lids. Its Neurologic Significance." David G. Cogan, M.D.

"Nutritional Retrobulbar Neuritis." Frank D. Carroll, M.D.

"Spectral Absorption Measurements of the

Refractive Media of the Eye." V. Everett Kinsey, Ph.D.

"Ocular Injury Due to Sulphur Dioxide." W. Morton Grant, M.D.

"Congenital Cataracts." Francis J. West, M.D.

At the November dinner meeting of the Cleveland Ophthalmological Club, Dr. Paul A. Chandler, assistant professor of ophthalmology in the School of Medicine of Harvard University, Boston, gave a most instructive and interesting paper on "Neglected Cause of Secondary Glaucoma in Which the Lens Is Absent Or Dislocated."

The annual meeting of the Ophthalmological Society of Egypt will take place at the Memorial Ophthalmic Laboratory, Giza, Egypt, on Friday and Saturday, March 14 and 15, 1947.

The following ophthalmic papers were presented before the Section on Ophthalmology and Otolaryngology of the Southern Medical Association in Miami, Florida, on November 6, 1946:

"Causes of Failure in Glaucoma Operations." Brittain Payne, M.D., New York (by invitation).

"Separation of the Retina—Technic and Results." W. R. Buffington, M.D., Louisiana.

"A New Syndrome: Vertical Phorias with Endocrine Dysfunction." E. H. Coachman, M.D., Oklahoma.

"Migraine as Seen by the Ophthalmologist." F. A. Holden, M.D., Maryland.

"Exophthalmos in Relation to Orbital Tumors. Report of Six Cases." S. B. Forbes, M.D., Florida.

The first meeting of the Washington, D.C., Ophthalmological Society for the 1946-1947 season was held November 4, 1946, and was a joint session with the Baltimore Ophthalmological Society. Dr. Richard W. Wilkinson, president of the society, presided during the meeting.

Case presentations were made by Dr. Edward J. Cummings on "Cataracta Neurodermatica," and "Vitreous Cyst." Dr. Jules B. Chapman presented a case on "Cataracta Complicata."

The guest speaker of the evening was Prof. W. J. B. Riddell of the University of Glasgow, Scotland. His presentation was on the "Clinical Valuation of Cataract Operation." Discussion on this interesting paper was made by Dr. Clyde A. Clapp of Baltimore and Dr. John W. Burke of Washington.

The next meeting of the society is scheduled for January 6, 1947.

The next meeting of the Pennsylvania Academy of Ophthalmology and Otolaryngology will be April 26 and 27, 1947, at the Penn-Harris Hotel, Harrisburg.

The Central Illinois Society of Ophthalmology and Otolaryngology held its sixth meeting at the Hotel Pere Marquette, Peoria, Illinois, on November 30 and December 1, 1946. The following ophthalmic papers were presented at the meeting:

"Partial Tendon Transplantation of Eye Muscles for Incurable Paralysis," Harry W. Woodruff, M.D., Joliet.

"Differential Diagnosis of Ocular Proptosis," Derrick Vail, M.D., Chicago (by invitation).

"Errors in Cataract Surgery," Watson Gailey, M.D., Bloomington.

"Surgical Management of Glaucoma and Glaucoma Problems," Derrick Vail, M.D., Chicago.

Guest speaker at the meeting was the Hon. Dwight H. Green, Governor of the State of Illinois. New officers elected for the year, 1947, include: President, Walter Stevenson, M.D., Quincy; president-elect, Clarence E. McClelland, M.D., Decatur; vice-president, Clifton S. Turner, M.D., Peoria; secretary-treasurer, William F. Hubble, M.D., Decatur.

PERSONALS

Dr. Phillips Thygeson, who since his discharge from the Army has located in San Jose, California, is now on the visiting staff of the University of California Medical School in San Francisco. Dr. Thygeson spends two days a week at the university carrying on his research work under funds from the Charles Taylor Reeves and Mrs. E. S. Heller donations. He has also been appointed to the staff of the Hooper Research Foundation.

Dr. John L. Scales, of Shreveport, Louisiana, announces his retirement after 50 years of active practice. At a reception in the Woman's Club on Sunday, November 3, 1946, some 500 guests, most of whom were physicians and their wives, paid their respects. Others present were members of the official boards of the various civic organizations of which Dr. Scales is a member, including the official board of Centenary College, and close friends.

Outstanding among those of the eye, ear, nose, and throat profession, Dr. Scales has endeared himself to an unusually large clientele, and because of his reputation for fair dealing, to all of his colleagues. Few physicians have been of such inestimable value to their communities, and news of his retirement comes with sincere regret.

Dr. William B. Clark, head of the department of ophthalmology, Tulane University of Louisiana School of Medicine, returned to Guatemala on November 7, 1946, where he concluded the research project on onchocerciasis that he began there last year.

AN INVITATION TO OPHTHALMOLOGISTS

The aim of the Guild of Prescription Opticians is to advance the science of ophthalmic optics through the development of a country-wide dispensing optical service which comprehensively meets the needs of the Eye Physicians and their patients and truly renders the most efficient form of services in eye care. The continued growth of this Guild is evidence of the success with which these unrelenting efforts have been accorded recognition.

Ophthalmology has evidenced its recognition of the important part Guild service has played in eye care because many of its members have joined at the suggestion and on the request of eye physicians.

The Guild extends to eye physicians an invitation to recommend dispensing opticians in their community who, in their opinion, conform to Guild principles. Full requirements for membership will be furnished upon request.

NUMBER 2

OCULAR HISTOPATHOLOGY OF SOME NAGASAKI ATOMIC-BOMB CASUALTIES*

T. F. SCHLAEGEL, JR., M.D.
Indianapolis

While stationed near Fukuoka, Japan, I had the opportunity of visiting the ophthalmological clinic of Kyushu Imperial University where the Japanese staff was involved in a study of the effects of the atomic bomb upon the eye. Although too late for a study of the clinical effects, I did arrive at the time of the pathologic investigations and was given sections of eyes obtained at autopsy. A study of these sections forms the basis of this report.

MATERIALS AND METHODS

None of the eyes studied clinically in Nagasaki were available for histopathologic study, but some were obtained at autopsy from patients who had died in other departments of the university as a result of the radiation sickness. I was given one to three sections each of six eyes of different patients plus one section of a lens, all stained with hematoxylin and eosin.

Unfortunately only one short clinical history on these patients was available (table 1), but it is typical, and aplastic anemia was an almost universal finding.

HISTOLOGIC CHANGES FOUND AT AUTOPSY.

Changes seen in the cornea and lens are apparently due to the direct effects of

radiation, while the findings in the rest of the eye appear to be secondary to the systemic condition. The positive histopathologic features are presented by cases. The numbering of these cases follows that of the ophthalmological clinic of Kyushu Imperial University.

TABLE 1
CLINICAL DATA ON THE 7 ATOMIC-BOMB CASES
SUBJECTED TO HISTOPATHOLOGIC STUDY

Number	Sex	Age	Eye	Days from Bombing to Time of Death
3	♂	30	OD	29
4	♀	—	OD	29
7	♀	7	OS	29
10	♀	36	—	30
15	♂	47	OD	32
27*	♀	54	OS	27
12	♀	19	OS	30

* Additional information is available on this case. It is reported not only for itself but also because it is roughly typical of the general clinical course. The original complaint was contusion of right leg. The history showed that the patient lived in wooden house 2 km. from the center of the bombing. For three days following the explosion, she vomited bilelike material and complained of anorexia and weariness. Epilation developed on August 15th. From August 31st on, she ran a fever of about 39.4°C. and had diarrhea. On admission to the surgical clinic September 3rd, she complained of pain in the entire abdomen. On September 4th she developed petechiae; the next day, she developed dyspnea and died. Laboratory findings were: Hemoglobin, 55 percent; erythrocytes, 1,790,000; leukocytes, 1,000. Autopsy showed: Petechiae of entire body, ulcer of right leg, epilation of head, ulcer of rectum; pulmonary hemorrhage, turbidity of parenchyma of liver and kidney, atrophic gastritis, slight enlargement of spleen, and adhesive fibrosis of pleura.

*From the Research Division and the Department of Ophthalmology of the Indiana University Medical Center.

CASE 3 (SLIDES A AND B)

Lens. Small vacuoles are seen under the anterior lens epithelium (fig. 1A), and in Slide B at one equator and at the posterior pole.

Choroid. There is a mild, loose, cellular infiltration, consisting mainly of small

Fig. 1 (Schlaegel). Case 3. A, There is a stratum of small vacuoles in the superficial anterior lens cortex. B, There is a mild, loose infiltration of mononuclear cells in the choroid (septic choroiditis).

lymphocytes, located in the posterior half of the choroid (fig. 1B).

CASE 4 (ONE SLIDE)

Lens. Small vacuoles in the lens cortex near its surface are seen anteriorly and posteriorly.

Choroid. There is a mild, loose cellular infiltration, consisting mainly of small lymphocytes, present in the posterior part of the choroid.

CASE 7 (SLIDES A, B, C)

Lens. Small vacuoles in the cortex at the equator are seen in two of the sections.

Ciliary body. In Slide B there is a mild edema of the ciliary processes.

Choroid. There is a moderate, loose mononuclear infiltration especially at the posterior pole.

CASE 10 (SLIDES A AND B)

Cornea. The epithelium is denuded

centrally, but peripherally a single layer of cells is present, probably representing regeneration (fig. 2A). A layer of fibrin containing bacilli is seen on the endothelial surface. These bacilli are single, stain faintly, and vary from 7 to 10 micra in length. There is a mild round-cell infiltration of the subconjunctival tissue at the limbus.

Iris. In Slide A there is edema with a mild, loose, round-cell infiltration.

Lens. In both slides a few anterior subepithelial vacuoles are seen.

Ciliary body. The vessels are packed with disintegrated leukocytes. There is a massive serous exudate in the suprachoroidal space. There are bacilli in the ciliary processes, a pink-staining edema of the superficial layers, and a layer of serous exudate on the ciliary epithelium.

Fig. 2 (Schlaegel). Case 10. A, The corneal epithelium is denuded centrally, but a single layer of cells from the periphery may represent regeneration. B, At the ora serrata is seen a massive serous exudate in the meshes of the suprachoroida extending under both the ciliary body and choroid.

Vessels of the flat portion of the ciliary body are filled with blood that has undergone autolysis.

Choroid. The massive serous exudate lying in the meshes of the suprachoroida extends back beneath the choroid (fig. 2B). The vessels of the choroid are filled with blue-staining granular material (probably autolyzed leukocytes). Bacilli of different sizes are seen in the large veins.

CASE 15 (SLIDES A AND B)

This eye presents a striking picture in that all the vessels are extremely distended by white cells. These leukocytes do not appear immature, and although there are polymorphonuclears and lymphocytes present, the great majority are mononuclear cells, the larger of which resemble macrophages. There is also a striking lack of erythrocytes, the white cells outnumbering them 10 to 1.

Cornea. The epithelium has been desquamated but appears to be regenerating. Fibrin fills much of the anterior chamber.

Sclera. Vessels of the sclera and episclera are packed with the white cells mentioned previously.

Iris. The vessels extending from the iris root are similarly distended.

Lens. There are anterior subepithelial vacuoles in the cortex. In Slide B numerous colloid excrescences are seen under the posterior capsule.

Ciliary body. The vessels of the entire ciliary body are packed with the leukocytes mentioned (fig. 3A).

Choroid. The most striking change is the severe distention of vessels by the same type of leukocytes (fig. 3B-C).

Optic nerve. At the disc the vessels are congested with the white cells, and along the nerve septa these cells appear to be mainly intravascular (fig. 3C).

Vitreous. It is of a definitely fibrillar

Fig. 3 (Schlaegel). Case 15. The vessels of the entire eye are distended with leukocytes, mainly mononuclears. A, Ciliary body. B, Retina and choroid. C, Retina, choroid, optic disc, and nerve.

structure complicated by the presence of fibrin in the region of the posterior retina.

Retina. The entire retina is atrophic and its vessels are distended with the cells described (fig. 3B).

In Slide A, five nodules of leukocytic, mainly round-cell, infiltration of the retina are seen (fig. 4). The pigment epithelium is disintegrating in many areas.

CASE 27 (SLIDES A AND B)

There is an invasion of the entire eye by streptobacilli plus an incidental old

Fig. 4 (Schlaegel). Case 15. A nodular leukocytic infiltration of the retina bulges up the internal limiting membrane.

iritidocyclitis with secondary glaucoma. The streptobacilli are extremely long consisting of up to 20 visible sections, each varying from 6 to 10 micra in length. They stain darkly with hematoxylin and have sharply sawed-off ends.

Episclera. It presents a mild leukocytic infiltration.

Iris. In Slide B, pigment granules, streptobacilli, protein exudate, and round cells are seen in anterior and posterior synechiae.

Lens. Streptobacilli are seen on the posterior surface in a serous exudate stretching from ciliary body to ciliary body (fig. 5A). There are small vacuoles under the anterior epithelium.

Ciliary body. The ciliary processes are atrophic. A thick layer of serofibrinous exudate is seen on the surface of the ciliary body and an inflammatory edema with streptobacilli is seen in the superficial portion.

Choroid. Long strands of morphologically identical streptobacilli are seen lying in the stroma and in the vessels amidst a mild edema.

Optic nerve. There is evidence of slight atrophy of the nerve with an increase of

Fig. 5 (Schlaegel). Case 27. A, Streptobacilli lie on the posterior surface of the lens in a serous exudate. B, A clump of streptobacilli in the inner retina lies under a heavy fibrin net three times as thick as the retina (only part of the net is shown).

neuroglial nuclei and apparent thinning of nerve-fiber bundles. The cribriform plate curves backward.

Streptobacilli are seen among the nerve and septal fibers. Colloid excrescences are present on the inner surface of the lamina vitrea which stretches across the optic-nerve head in this peripheral section.

Vitreous. Several large preretinal fibrin nets are seen.

Retina. Streptobacilli lie in the ganglion cell and nerve-fiber layers (fig. 5B). A cystoid degeneration at the ora serrata involves both layers. (The age of the person in this case was 54 years.)

CASE 12 (ONE SECTION OF LENS)

The entire lens is shrunken. Relatively

large vacuoles are present in the anterior cortex and a few are seen in the posterior cortex. At one equator in a deeply pink-staining homogeneous material are found a number of large vacuoles. This pink material is probably albumin which has exuded from the lens fibers and collected under the loosened and wrinkled capsule as a postmortem phenomenon.

COMMENT

CORRELATION OF REPORTED CLINICAL FINDINGS WITH HISTOPATHOLOGY

It has always been difficult to correlate clinical findings with those of the microscope. The following comments will be in the nature of speculation, especially since none of the eyes observed clinically were available for pathologic study.

In general the damage to the eyes was less than that to other organs. The usual blast and foreign-body injuries were seen early but with the unique addition of burns from infrared and ultraviolet rays.¹

Cornea. Conjunctivitis and superficial keratitis were found in many of the patients, but the effects disappeared in about a month.¹

In some of the sections (one month after bombing) there is found a denudation of the epithelium with regeneration. This corneal damage was apparently due to the direct effects of irradiation and was clinically considered due to ultraviolet rays.¹

Sclera. Episcleritis in conjunction with corneal infiltration was found in some cases.¹

Although there is no stromal damage, an occasional infiltration of the episclera by leukocytes is seen.

Iris. There is no report of clinical involvement, and in only one case is there a mild edema and cellular infiltration.

Lens. Flick,² using an ophthalmoscope, found no cataractous changes. Professor Shoji (Tokyo) in a letter to Ikui said

that after examining the patients in Hiroshima he found one cataract that developed 40 days after the bombing. Experimentally it has been demonstrated that changes appear histologically before they can be detected clinically.

There are variations in the reported histologic findings, but the following arbitrary outline will serve as a guide for comparison.

REPORTED LENS CHANGES OBSERVED

1. Vacuoles in both the anterior and posterior subcapsular cortex.³ The size of vacuoles in these cases is greater than that commonly seen in routine eye sections, but less than that frequently reported.

2. Vacuoles are at first discrete but later coalesce to form plaques.⁴ In the sections they appear to be in the process of forming plaques.

SOME REPORTED LENS CHANGES NOT OBSERVED

1. Later there is a knotty swelling of fibers at the equator which extends over the entire posterior cortex.³

2. A change in the curve of the lens epithelium and a movement of nuclei backward to form a pseudoepithelium.³

3. Metaplasia of the anterior epithelium.^{3, 5}

These changes not observed are late alterations and would not be expected after one month. In man the latent period for irradiation changes has varied from 9½ months to 8 years,⁶ and even in experimental animals it has never been as short as one month, as far as I can determine.

According to Rohrschneider, no lens changes can be produced with less than an epilation dose of irradiation, but Lebensohn⁷ and Kandori⁸ maintain that they can. Epilation was common among the Nagasaki people with irradiation sickness,

so it appears very possible that these eyes sectioned received a dose sufficient to produce radiational cataract, but time for complete development had not elapsed.

From the standpoint of roentgens it is impossible to state whether the computed 473r at 1,250 meters⁹ was sufficient to cause cataract, for roentgens are not a reliable index of biologic effect, and we

cut, although they appear to be from near the axis. The fact that the measurements at the equator are less than those of the reported normals may indicate that there is no error from over measurement.

Another check on the figures obtained is to compare them with Fincham's diagrammatic construction of the lens capsule.¹² From Table 2 we find a 50-percent

TABLE 2

* The anterior and posterior extremities of the lens were considered the respective poles. This assumption introduces an error which is discussed.

† Unknown because age of patient is unknown.

‡ Not measurable because of indistinctness or absence.

have only one short clinical history. It is known that gamma radiation is very apt to produce cataract,¹⁰ and gamma rays were present at Nagasaki.⁹

Experimentally, the anterior capsule may become thickened to twice the normal size.⁴ A study of the thickness of the capsule of these Nagasaki cases was made and the figures obtained compared to those of Salzmann¹¹ (see table 2). The anterior and posterior extremities of the lens were considered the respective poles and measurements were also taken at both equators. The assumption that we are dealing with sections through the poles introduces an error, for it is impossible to tell exactly where the sections were

increase in thickness of the anterior capsule over that of the normal at the pole. If we consider the figure as indicative only of eccentricity of the sections, we find that its 50-percent increase in thickness corresponds to a point about 1.3 mm. from the center of the lens. From their appearance it is probable that my sections were cut in roughly this area. At the same distance from the axis on the posterior capsule, we may compute that the thickness of the capsule is at least 200 percent greater than would be expected. It appears safe to conclude that the posterior capsule is thickened, but the apparent increase in thickness of the anterior capsule is in the realm of error be-

cause of the eccentricity of the sectioning.

It is obvious that the lens picture bears only slight resemblance to the reported changes in roentgen-irradiation cataract. The evidence we do have rests on the findings of small vacuoles in the superficial cortex and a thickening of the posterior capsule. (It is the anterior capsule which has been reported as becoming thickened, and anoxia may have played a role in the production of the lens vacuoles.)¹³

Although the evidence is inconclusive, we could expect little change after only one month. It will be interesting to see what later clinical and histologic studies of the atomic-bomb survivors will show in respect to the development of irradiation cataract.

Ciliary body. Degeneration of the ciliary epithelium observed experimentally⁸ was not seen.

A mild edema of the superficial loose tissue was commonly present, and in the last three cases a serous cyclitis was observed. In Case 10 there was a serous detachment of the ciliary body and choroid of severe degree. The serous character of the involvement is the prominent change. It is possible that these patients suffered from a decrease in plasma protein from inanition as a result of vomiting, diarrhea, and anorexia. The lowered colloid osmotic pressure plus damage to the capillary endothelium from severely anemic blood could have led to the serous exudation observed. The direct effects of radiation may have played a role, but characteristic radiational damage was not detected histologically.

Choroid. A severe serous detachment is commonly the result of considerable reduction in the intraocular pressure. There is no such information in Case 10 although the fibrin and bacilli in the anterior chamber may have resulted from perforation.

Septic choroiditis which consists of

loose accumulations of mononuclear wandering cells in the stroma of the choroid from septicemias of various types,¹⁴ was found in the first three cases of this report. Although bacteria were not found in the tissues, the possibility of their presence in the eye is good, in view of the bacterial invasion in two other cases.

No choroiditis was observed clinically but this is to be expected from the mild character of the involvement.

The striking distention of the vessels of the entire eye by white cells in Case 15 is most pronounced in the choroid. These cells are mainly mononuclears and do not appear immature. I can find no theory to explain adequately this unusual reaction. The number of white cells is greater and the number of red cells less than could be explained by the manipulation upon removal. Although a regenerative process which overshoots its mark after roentgen irradiation may give rise to an increase in mononuclears,¹⁵ such an excessive regeneration seems unlikely in view of the lack of a leukocytosis in other patients, and in view of the fact that the leukocyte count would have had to have been in the hundreds of thousands. Leukemia has occurred after radiation,¹⁵ but these cells do not appear leukemic.

Optic nerve. No important changes in the optic nerve were observed either clinically² or pathologically.

Retina. Flick² found the retinal vessels to be normal and this is true in these sections.

The eyes in this series were obtained at autopsy, and eyes so obtained will show autolysis of the retina. The generalized atrophy in Case 15 may have been due to postmortem autolysis or to a local anoxemia caused by the white cells crowding out the red cells plus a stasis of circulation.

Clinically, edema of the retina was common² but definite evidence is lacking histologically. Exudates were common. They

were round, snow-white, slightly elevated, and obscured the retinal vessels when lying over them.² It is possible that they were nodules of leukocytes such as is shown in Figure 4. This nodule bulges up the internal limiting membrane and could be correlated with the elevated appearance seen clinically. The feathery edges might have been due to the presence of cells at the periphery of the nodule where they would be thinned out and separated by nerve fibers. Also the round character of these spots correlates well. There are more probable causes of such exudates, but no other plausible explanation is apparent from a study of the tissues available.

Some of the exudates seen by Flick were elongated and often of a peculiar zig-zag formation in which the extension in length was perpendicular to the direction of the nerve fibers.² It is possible that these peculiarly shaped figures were due to heavy masses of fibrin next to the external limiting membrane. This could explain their character of running cross grain to the nerve fiber bundles.

There is no evidence of the retinal hemorrhages seen clinically.

BACILLI

The patient in Case 27 was the one with the remarkable invasion of the eye by streptobacilli. This person was found to have an ulcer of the leg and an ulcer of the rectum on postmortem examination. The gastrointestinal tract is most sensitive to radiation,¹⁶ and complaints referring to it were almost universal. Burns and cuts were also common. It is possible, therefore, that bacteria made their entrance through one or more of these portals and disseminated throughout the body just before death. The lack of leukocytic response to their presence supports the assumption of a terminal bacteremia. It is postulated that these bacilli remained

in the tissues where they grew and hastened the process of postmortem autolysis until stopped by the fixing agent.

THE ATOMIC-BOMB RADIATION

According to Larkin,⁹ the disintegrating products of plutonium fission consist of fission fragments, neutrons, and beta particles, and a transformation of the remainder into heat, gamma rays, and radiant energy which includes ultraviolet, visible, and infrared radiation. Since these products produce similar reactions in the body, it is difficult to say with certainty what part each of these products played.

The radiation sickness seemed to be similar to that usually seen with heavy total-body irradiation.⁹ Its principal effect was on the bone marrow resulting in aplastic anemia.¹⁷ The average patient complained of fever, malaise, loss of appetite, bleeding gums, and hemorrhagic diarrhea.¹⁶

By a process of calculation, Larkin concluded that there were 473r/sq. cm. at 1,250 meters from the point where the bomb was dropped.⁹ Irradiation of the entire body with 500r will kill.¹⁸

Except for changes in the cornea and lens, no definite evidence of direct damage by radiation was observed. It is probable that the Japanese who received severe whole-body irradiation died before any severe local manifestations could be observed.

There are certain histopathologic features of the effects of radiant energy on general body tissues which, when taken in combination, are characteristic. These are the presence of giant and irregular nuclei, the presence of hyaline connective tissue, and the presence of thick-walled hyalinized blood vessels.¹⁸

None of these features was seen.

SUMMARY

Sections of eyes of patients who had

died from the effects of the Nagasaki atomic-bomb irradiation one month after the bombing were studied. The histologic changes may be grouped into those apparently due to direct irradiation and those due to the systemic condition.

The cornea and lens may have been damaged by direct irradiation. Some of the corneas are found to be denuded with evidence of epithelial regeneration. The lenses may be in the early stages of developing radiational cataracts as evinced by small vacuoles in the superficial cor-

tex and a thickening of the posterior capsule.

The following changes were due apparently to the patient's systemic condition: (1) serous exudation into and from the ciliary body; (2) invasion of the eye by bacilli; (3) septic choroiditis; (4) nodular cellular infiltration of the retina; (5) fibrin nets on the surface of the retina; (6) and, in one case, a striking distention of all the ocular vessels by white cells, most of which were mononuclears.

1040 West Michigan Street (7).

CORNEAL LESIONS IN HODGKIN'S DISEASE

REPORT OF A CASE*

P. MATTEUCCI, M.D.†

Rome, Italy

All that is known of the histology and clinical appearance of the malignant lymphogranulomas combines to define it as a disease of unknown etiology, characterized histologically by an inflammatory process of the prevalent productive type affecting essentially the reticulo-endothelial tissue, evincing a predilection for that of the lymph glands, and leading to the formation of a specific granular tissue (Cionini).

Although there is the possibility of its involving any and every organ and tissue in the body, Hodgkin's disease shows a conspicuous predilection for those structures wherein the reticulo-endothelial system is chiefly represented; hence, the lymph and hemopoietic organs are most frequently involved. Nevertheless, the process does not affect the parenchyma of these organs directly, but only the stroma, as is true also of all organs and tissues that are included in the lymphohemopoietic system.

Thus, Sternberg's cells can readily be found in the lymph glands, the spleen, and the bone marrow; in the liver, mediastinum, and lung, and, with varying frequency, everywhere in the gastro-intestinal tract, as well as in the small and medium intraparenchymal blood vessels.

They are found somewhat less frequently in the skeletal system, the pericardium, pleura, skin (specific lesions), and in some of the endocrine glands (thyroid, adrenals, pancreas).

Foci are seldom situated in the muscular system, the uropoietic and genital ap-

paratus, in the thymus, and the nervous system.

Granulomatous changes involving the heart and large blood vessels, the mucous membrane of the mouth, pharynx, tonsils, esophagus, and rectum are rarely found. In exceptional instances, a granulomatous nidus has been observed to occur in the hypophysis (Graf, Cacciamali).

As to the visual apparatus, direct lesions have been infrequently reported as occurring in the orbit, the lacrimal gland, and the eyelids (Mueller, Ridley, Dutoit, Hoeckel, Colrat), the conjunctiva (Dellille, Cocchi), the fundus (Hegner, Heine, Kyrieleis, Sachs, Bell, Mariotti), and the cornea (Sachs, Morax, Lagrange).

The rarity of ocular involvement in Hodgkin's disease may be due to the scarcity or absence of the reticulo-endothelial system in the various structures of the eye. In effect, it is entirely absent in the vitreous, lens, and aqueous humor but occurs abundantly in the choroid and, to a somewhat less degree, in the pigment layer of the iris. The sclera has scarcely any, and this is also true of the retina in spite of the vascularity of the latter, whose cells contain none whatever. Recently, Gasteiger and Ciotola, although they have not established the existence of reticulo-endothelial elements in the cornea, have found in keratitis certain cellular elements that have taken the supravital stain and were, therefore, considered as belonging to the reticulo-histiocyte system.

In view of the infrequency of ocular complications in Hodgkin's disease, the following occurrence of such an involv-

* From the Ophthalmological Clinic, Professor Cavara, director.

ment is described from the case histories of the Ophthalmological Clinic of the University of Rome, through the kindness of Professor Cavara, its director.

CASE REPORT

History. T. A., a housekeeper, aged 27 years, gave no history of parents and relatives, but mentioned that she had had typhoid fever at the age of 11 years; that thereafter she had been in good health; and that she had married a man apparently of sound health and had had several sons.

In the spring of 1939, she had not been so well, had had a little fever, and noticed a tumefaction of the glands of the neck. The physician diagnosed the condition an anemia and gave her treatment. Some months later, physicians in Perugia made a biomicroscopic examination of the cervical lymph glands and advised her to have X-ray treatments. These gave much relief. Later, she went to Rome where, for about a year, she was well.

Early in 1942, while her health was again failing, she noticed a tumefaction of a gland on the left side of the neck. She was given a thorough physical examination by a physician, including: X-ray study of the chest and Wassermann, tuberculin, and morphologic blood tests. As a result, she was advised to take a second series of X-ray treatments, which again cleared the condition, generally and locally. Before long, however, a new growth appeared, this time in the right axillary region. This again was successfully treated, but later a growth appeared in the left axilla, accompanied by itching and irregularity of the menses.

In February, 1943, the patient first had trouble with her eyes: photophobia, lacrimation, and diminished vision of the right eye. In June, on Professor Cavara's advice, she entered the Clinic.

Ocular examination. The cornea of the

right eye presented a superficial zone of infiltration with irregular, somewhat wavy edges. There was partial loss of the epithelium and marked hypoaesthesia. The iris was somewhat congested. The left eye, near the lower limbus, had two smaller zones of opacity with the same characteristics as those of the right eye. From the lower opacity, a line of superficial infiltration branched off toward the corneal center. There was evident hypoaesthesia. The iris was considerably congested, with marked pericorneal injection.

In general, the keratitis, although not presenting well-defined characteristics, had a herpetiform appearance. Experimental test on a rabbit's cornea, however, was negative.

After more than a month of treatment—iodine, atropine, dionine, urotropine, and endovain—the patient was dismissed because of the air raids. Her condition had improved a little; in fact, the cornea of the right eye showed a dissipation of the superficial infiltration; the ciliary reaction was still present. In the left eye, the cornea was opaque in the lower peripheral sector, especially deep in the stratum, the infiltrative process having, in the meantime, reached the parenchymal strata. Descemet's membrane was not wrinkled.

In September of 1943, after another series of X-ray treatments to the lymph glands, the patient was remarkably improved, even as to the eyes, and for a few months required no special treatment. The general and local conditions remained almost stationary until February, 1944, when the patient again came to the Clinic. Professor Cavara noticed a new congestion of the left eye. He thought the patient should be given a general examination and the blood picture defined morphologically. She, therefore, came to the Clinic of the University of Rome. The medical examination confirmed the

diagnosis of Hodgkin-Sternberg disease.

The blood picture was as follows: Hb., 56 percent; R.B.C., 4,000,000; C.I., 70; W.B.C., 14,000, of which polymorphonuclears comprised 80 percent; endothelialocytes, 10 percent; lymphocytes, 10 percent. The red blood cells showed little, if any, poikilocytosis.

Further ocular findings. Right eye. The adnexa were normal. There was a slight

terior surface of the cornea was seen to be slightly irregular and strewn with small, pointed, gray spots with irregular edges, some confluent, some arranged in thin, wavy lineal streaks. Tested with fluorescein, many of these spots took on color. In places, the corneal parenchyma appeared to be normal; in the more opaque zones, a light infiltration of the most anterior strata of the parenchyma

Figs. 1 and 2 (Matteucci). Fig. 1, Drawing of the left eye. Corneal thickness is reduced, and infiltration is so dense as to give the appearance of a well-developed lesion. Thin, aborescent vessels from the limbus are advancing into the cornea.

Fig. 2, With the slitlamp beam well-narrowed, the posterior surface of the cornea is seen to be irregular and somewhat prominent toward the anterior chamber.

pericorneal injection. By oblique illumination, a zone of slight turbidity was observed. It had irregular edges and included the left lower portion of the pupillary space and the lower part of the cornea. The turbidity was not homogeneous but in places was intense, elsewhere less so. Some of the turbid zones had a dislike aspect with blurred edges, 3 to 4 mm. in size. In the opaque zone of the cornea, the surface was not lustrous and smooth but appeared roughened; this was confirmed by examination with the biomicroscope.

By means of this instrument, the an-

terior surface of the cornea was seen to be slightly irregular and strewn with small, pointed, gray spots with irregular edges, some confluent, some arranged in thin, wavy lineal streaks. Tested with fluorescein, many of these spots took on color. In places, the corneal parenchyma appeared to be normal; in the more opaque zones, a light infiltration of the most anterior strata of the parenchyma

was observable. This could best be viewed by means of a very slender pencil of light. In addition to these zones of corneal infiltration, which were thought to be actual lesions, granular in appearance and having blurred edges, there were others with more sharply defined borders, probably the result of the older lesions observed in July, 1943. There was evident hypoesthesia. The iris was slightly hyperemic. The pupils were round and reacted promptly to light and accommodation. Lens, vitreous, and the fundi were normal. Corrected vision, with a -1D.

cyl. ax. 80° was 6/10. The ocular tension was normal.

Left eye (figs. 1 and 2). The adnexa were normal. There were slight photophobia and pericorneal injection. Upon examining the cornea with focal illumination, a wide zone of corneal opacity was observed, affecting the central and lower portions. In this eye, also, the opacity was not homogeneous but varied in intensity. This was especially observable at two points: (a) in the peripheral part, where there was a zone of denser opacity, semi-lunar in form, parallel to the limbus, 6 to 7 mm. long, about 2 mm. wide, and at 2 to 3 mm. distance from the limbus; (b) in the central part was another, more densely opacified, round portion, 1 mm. in diameter. The surface of the cornea over this lesion was irregular, as described with respect to the right eye.

Upon slitlamp examination, the corneal parenchyma of the left eye was seen to be much more involved than that of the right eye. Indeed; whereas, in the right eye there were zones where the epithelium was affected and some where the infiltration of the parenchyma was sharply limited to the immediate subepithelial stratum, in the left eye, the turbidity affected the parenchyma throughout its entire thickness.

In the left eye, the following changes were observed: the corneal thickness was reduced, the infiltration being so dense as to give the appearance of a lesion well advanced, if not entirely developed. This infiltration was especially marked in the deeper strata. With the beam well narrowed; the posterior surface of the cornea was seen to be irregular and somewhat prominent toward the anterior chamber. Thin, arborescent vessels from the limbus advanced into the cornea, some superficially, others more deeply. On the posterior surface of the cornea in the (a) zone, and exactly corresponding to its thin

part, three or four masses of flattened and amorphous pigment could be seen. In the (b) zone, the infiltration seemed to be of an entirely recent process and more marked in the layers straddling Descemet's membrane, but it differed from (a) in that the thickness of the cornea was normal. Here there were no newly-formed vessels. The cornea was hypoes-thetic. The anterior chamber was normal as to depth; the aqueous clear. The iris was slightly hyperemic; the pupil round, and its reactions normal. The posterior segment was normal. The corrected vision, with a $-75D$. cyl. ax. 90° , was 4/10.

The patient was seen occasionally during the following months, but the corneal lesions showed only slight alterations during this time. The evolution of the lesions was somewhat slow; the clinical aspect changed but little. Both eyes were slightly photophobic. Fluorescein staining of the epithelium, in the right eye especially, had almost disappeared, but the gray spots were still observable; evincing a greater tendency to confluence, to form thin, irregular streaks in large curves. The deep infiltration especially in the left eye, was reduced in intensity. On the patient's last visit, the epithelial streaks had assumed a dendritic aspect, resembling the dendritic keratitis of herpes. The parenchymal lesions were slowly improving.

DISCUSSION

From what we know of the literature, only one case of Hodgkin's disease has been reported showing corneal changes of the type just described; namely, the case reported by Sachs, which in many of its features is similar to the one I have observed. Lagrange's and Morax's cases differ basically because of the morphologic characteristics of the corneal lesion.

Sachs gives a good description of a

bilateral keratitis of long standing in a patient with malignant lymphogranuloma. The corneal involvement was characterized at the beginning by superficial marginal infiltration, erosions, and small gray spots of a herpetic type, but without corneal hypoesthesia. Subsequently, this writer observed the formation of a deep ulceration followed by a keratitis of dendritic type and, at last, a superficial vascularization. The ocular condition, followed over a period of many years by this author, suffered alternatives of remissions and exacerbations, and seemed to be much improved by treatment of the glandular affection with the X ray.

Lagrange speaks of an interstitial annular infiltration of the cornea with successive thrusts into the depth and of the coexistence of a limbic, deep vascularization radially disposed, similar to the one presented by inherited syphilitic interstitial keratitis; even in this case, lesions seemed to improve with X-ray application. Morax, lastly, in a patient in whom lymphogranuloma could not be definitely diagnosed because of the many lacunae of the general examination, found a circumscribed episcleritis that eventuated in parenchymal infiltration of the cornea.

Regarding the clinical case just described, it is important to note, from the general point of view, the rising, the regression, and the duration of the glandular tumefactions; the clinical response, the absence of reactions to tuberculin, the negative Wassermann reaction, the morphologic blood picture, the influence of X ray on the glandular tumefactions and on the general condition of the patient. All these observations point to a diagnosis of Hodgkin's disease.

As to the nature of the keratitis found in this patient, it is important to note that the polymorphic aspect of the corneal lesions, the renewed exacerbations, and the long course were reminiscent of the many

aspects of herpetic keratitis. This herpetic form aspect was much more evident in Sach's cases. Nor is there any contradiction in the fact that in our patient's left eye there was a deep infiltration also, for it is well-known that, among the cases presenting typical corneal lesions of the dendritic type, no morphologic aspect is pathognomonic of corneal herpes.

One need only consider superficial punctate keratitis and disciform keratitis, forms not at all resembling the classical aspect of corneal herpes and actually representing syndromes in which a herpetic etiology occupies an important place (Cavara).

Cavara and others have also demonstrated that herpetic virus can produce parenchymal infiltration of the cornea not of the disciform type. In the present case, however, it must be remembered that the biologic test of the rabbit's cornea was absolutely negative, and it is not known that the patient was ever subject to herpetic eruptions on lips and face. A syphilitic cause cannot be the basis of this keratitis because the clinical aspect was entirely different and the frequent serologic blood examinations were always negative. On the other hand, the bilaterality of the affection, the lack of reaction to tuberculin, and the absence, or nearly so, of corneal vascularity indicate that the disease is not tubercular in nature.

It is not possible that the corneal lesions in this case would be due to any of the widely known agents capable of producing keratitis, and not a single such proof has come out of the few cases described by the preceding investigators.

At this point, it might be well to recall the frequent association, noted by many writers, of Hodgkin's disease with herpes zoster. In the histories of malignant lymphogranulomas, herpes zoster is very often present during the illness; similar cases have been observed by many writers

(Vattuone, Burnam, Weismann, Netter, Schreus, Middleton, Goldman). The first to call attention to the appearance of zoster during Hodgkin's disease were Pancoast and Pendergrass, who observed four cases; following these were Baldrige and Awe, with 6 cases in 46 of lymphogranuloma; Craver and Cushman, 3 cases in 72; Porta, 4 in 50. This recorded incidence would lead one to think that the appearance of herpes zoster during Hodgkin's disease is not a casual coincidence. Many pathogenetic hypotheses have been drawn up on the basis of this record. Some of these admit the existence in lymphogranuloma of anatomic alterations of the spinal ganglia or posterior roots favoring the culture of the unidentified zosterian virus. Another hypothesis maintains that lymphogranuloma represents a condition conducive to the thriving of the zosterian virus on spinal ganglia, independent of the presence or absence of resultant lesions. In view of the fact that up to this time no demonstration of an anatomic lesion of ganglia has been made, a hypothesis less susceptible to criticism and one most widely accepted seems to be to consider lymphogranuloma as a morbid condition which particularly favors the thriving of zosterian virus on spinal ganglia, independently of lesions of any nature in the ganglia themselves (Cionini). Nevertheless, the keratitis observed in our case and in those previously described as in association with Hodgkin's disease did not have the characteristics of a zosterian keratitis. The latter is more typical of keratitides, due to a virus of herpes febrilis, nor have there ever been eruptions of herpes zoster on the skin.

It is, therefore, possible that the ocular affection of our patient can have an etiologic connection with the primary disease; that is, malignant lymphogranuloma. Among the facts that focus the attention

on such a possibility, the most important are the rising of corneal lesions during Hodgkin's disease and their remarkable amelioration as the result of irradiation of the lymph glands.

As to the cause of malignant lymphogranuloma, it is well-known that, whereas today those who advocate a tubercular etiology are becoming fewer, the infective nature of the affection is gaining more and more acceptance. A group of researches, begun in 1933 by Gordon, on the cause of lymphogranuloma has revealed biologic phenomena deserving of the most careful consideration, even if they could not effect a conclusive solution of the problem. According to these writers, the lymph glands affected by Hodgkin's disease contain an active principle (virus or ultravirus) capable of determining a meningo-encephalitic picture if injected endocerebrally into a rabbit. According to other writers, this substance could be a necrocytotoxin with a particular liking for the cerebral substance of rabbit and cavia; and, according to still other writers, a substance of an enzymelike nature, very similar to that extracted from leukocytes, bone marrow, and spleen of subjects not affected by malignant lymphogranuloma.

Recent data on the etiologic agent of inguinal lymphogranuloma allow its classification in the group of ultraviruses, according to Magrassi. Researches on the causal agent of malignant lymphogranuloma introduce an element suggestive of an analogy with this group of infectious agents and, day by day, this analogy is growing in importance and extent. Researches up to now have not clearly demonstrated a virus to be the etiologic agent of malignant lymphogranuloma, but the hypothesis has a great deal of probability.

In this hypothesis, there is nothing contradictory in the admission that the keratitis observed in Hodgkin's disease is due,

etiologically, to the virus of the primary disease that would be capable, together with a number of other viruses (fever herpes, zoster, epidemic parotitis), of causing corneal lesions more or less characteristic.

CONCLUSIONS

Of the many reasons mentioned for presenting this account of a herpetic type of keratitis appearing in the course of Hodgkin's disease, the following are the most important.

1. The rarity of the occurrence as reported in the literature.

2. The effect of general radium therapy on the course of the ocular lesion that would confirm the radium sensitivity of specific cells of malignant lymphogranuloma.

3. Probable etiologic association that seemed to exist between the supposed virus of lymphogranuloma and the corneal lesions described.

THE MARCUS GUNN PHENOMENON

DISCUSSION, PRESENTATION OF FOUR INSTANCES AND CONSIDERATION OF ITS SURGICAL CORRECTION*

EDMUND B. SPAETH, M.D.

Philadelphia

The Marcus Gunn phenomenon, that is, congenital ptosis with an associated jaw-winking reflex, is not an uncommon finding. In two series of consecutive cases of congenital ptosis, it was present in 2 percent of the first 100 cases seen; and in the next 50 cases seen, 2 additional instances appeared. It therefore has an approximate incidence of 2 percent of all cases of congenital ptosis. The symptom complex is essentially an intermingling or misdirection of developing fifth-cranial-nerve fibers, and perhaps tracts, and the oculomotor-nerve fibers. All degrees of the condition are frequently seen, some so slight in amount that they are overlooked. The only cases which come to the attention of the ophthalmologist or of the neurologist are those with ptosis of such a marked degree that relief is sought for the ptosis.

According to Bing and Haymaker,¹ the Marcus Gunn phenomenon occurs not only in cases of congenital ptosis, but also in individuals with acquired ptosis and in some, as was just stated, who are free of ptosis. The term "Marcus Gunn phenomenon" should be applied only to the congenital cases. The term "pseudo-Graefe syndrome" has long been connected with and considered as the proper term for this condition when acquired, involving as it usually does, the levator and resulting from the misdirection of regenerating third-nerve fibers.

The basic premise of this presentation

is a discussion of the Marcus Gunn phenomenon. The consideration of the acquired form of pathologic associated reflexes, as seen with the pseudo-Graefe syndrome, will be of assistance in helping to understand the basic subject. Some other pathologic associated reflexes seen, and relevant, are the contraction of the orbicularis associated with movements of the jaw; the contraction of the levator with adduction or abduction of the eyeball; the rather unpleasant contraction of various facial muscles which one sees after an acquired facial paralysis; and the syndrome of "crocodile tears" with and after a facial paralysis.

There is but little doubt that the pseudo-Graefe syndrome is a frank peripheral misdirection of regenerating third-nerve fibers. Figure 1² shows such a situation wherein, as the result of a fracture at the base of the skull, a complete third-nerve palsy developed. Some time later, when maximum spontaneous recovery had ceased, the patient presented a paralysis of left upper rotation; paresis of left internal rotation; a dilated pupil; a variable ptosis; and downward rotation was limited to some degree. The ptotic lid lifted strongly with downward or internal rotation; also with downward rotation, the fixed dilated pupil contracted almost to the normal. In the process of regeneration of the third-nerve fibers, certain fibers destined for the inferior and the internal rectus muscles had found their way from the point of sectioning into the neural sheath of fibers normally bound for the levator. Also fibers normally destined for the inferior rectus terminated in the sphincter iridis.

* Graduate School of Medicine, University of Pennsylvania, and the Wills Hospital, Philadelphia. Presented before the Section of Ophthalmology, Illinois State Medical Society, Chicago; September 14, 1946.

Fig. 1 (Spaeth). Pseudo-Graefe syndrome. (Spaeth, E. B. *Ophthalmic Surgery*. Philadelphia, Lea and Febiger.). Paralysis of superior rectus, paresis of internal rectus, paresis of inferior rectus, associated elevation of levator with downward and internal rotations C and D. Complete ptosis with left lateral rotation. Contraction of pupil can be seen in C.

In an instance such as this, there must have been some type of break in the continuity of the fibers as they lay within the trunk of the third nerve. This must have occurred at some place before the third nerve divided into its two major divisions, in all probability intracranially, but certainly after the emergence of the

trunk of the nerve from the brain stem. A complete third-nerve paralysis unilateral, involving both the intrinsic as well as the extrinsic muscles of the eye, without any contralateral pareses whatsoever, has, perhaps, as the most common etiology, a vascular situation either connected with the Circle of Willis, or with the posterior cerebral artery. Because of that, some too much regeneration (no matter how complete this may be) is always a possibility. During that process of regeneration, some twisting can occur to the trunk of the nerve from small bands of organized cicatricial tissues resulting from the trauma and causing the misdirection of the fibers within the trunk itself.

According to Helfreich and Bernhard,³ the Marcus Gunn phenomenon can be explained only on the basis of neuronal intercommunications between the nuclei of the facial, trigeminal, and oculomotor nerves, or as a result of a cortical or subcortical (Bing¹) pattern analogous with the Bell's phenomenon. Such an intercommunication has more recently been denied by Lewy, Grant, and Groff.⁴ Obviously neither a cortical ocular reflex arc nor an intranuclear connection of the oculomotor nerves could be affected by an extramedullary sectioning of the fifth nerve to the pterygoids. These investigators (Lewy, Grant and Groff) state that the Marcus Gunn phenomenon is completely abolished by sectioning the motor root of the trigeminal nerve, but that with forcible movements of the jaw, postoperatively, the associated movements of the eyelid could still be elicited. This suggested to them the presence of a proprioceptive arc, the afferent limb of which (at least in part) was the sensory portion of the mandibular division of the trigeminal nerve. They assumed that the efferent part of the arc, that which passed to the eyelids, was via autonomic fibers whose path-

way was undetermined, but thought to be via the ophthalmic division of the trigeminal nerve. There is no controversy as to the afferent pathway, but there seems to be some logical doubt relative to the efferent portion of the arc. The question cannot be answered with entire satisfaction without considering the possibility of some brain stem, intramedullary infranuclear communication, as originally suggested by Helfreich and Bernhard.

The observation of Lewy, Grant, and Groff can be answered in part, perhaps, upon the basis of Cannon's law of denervation. This states, according to Walsh,⁵ that postganglionic, and to a lesser degree preganglionic, sectioning of a nerve results in increased sensitivity of the innervated structure to chemical modification, whether or not that substance be sympathin or acetylcholine. The sensitivity persists providing that regeneration does not occur, and that the innervated structure does not become atrophic. Hence it would be unnecessary to assume the proprioceptive reflex arc, with the efferent portion they outlined as still intact, as a reason for the condition.

Lewy, Groff, and Grant did a great amount of experimental work on cats; first, however, sectioning the oculomotor nerve. These studies included the effects of acetylcholine, of nicotine, of epinephrine, and of atropine, the effects of faradic stimulation upon the peripheral stump of the previously sectioned nerve, upon the gasserian ganglion and its three divisions under varying circumstances, and the effects of chemical and electrical stimulation of the cervical portion of the sympathetic trunk; all these as they reacted after the third nerve had been cut for at least 12 days.

Two cu. mm. of acetylcholine were injected into the right carotid artery. This injection was finished in 15 seconds, but an enlargement of the palpebral fissure

continued for an additional 10 seconds. This portion of their study, therefore, is a confirmation of Cannon's law of denervation and has nothing to do with possible intraneural connections. The other findings were not as conclusive, however. In it three phases of widening of the right palpebral fissure were shown subsequent to faradic stimulation of the peripheral stump of the sectioned first division of the fifth nerve. The right oculomotor nerve had been divided 16 days before this experiment. There was a return to the original position of the lids 25 seconds later. Electric stimulation of the peripheral stump of the previously sectioned third nerve, regardless of the strength of the current, failed to produce any reaction whatsoever whether 7 or 42 days after sectioning of the third nerve.

Electric stimulation of the gasserian ganglion with the root and its branches intact produced slight widening of the ipsilateral fissure, also after sectioning of the second and third division, but after sectioning of the first division stimulation of the ganglion became ineffective. Stimulation of the stump of the first division produced the phenomenon, but stimulation of the stumps of the second and third divisions did not. Insofar as this part of their study is concerned, there is some definite connection between a muscle controlling the width of the palpebral fissure and the first division of the fifth nerve, but whether it is sympathetic or somatic cannot be answered on these findings. Sympathetic stimulation can widen the palpebral fissure appreciably and quite readily in the presence of a completely paralyzed levator, as has been demonstrated experimentally as well as clinically. It seems that the observations of Lewy, Grant, and Groff in this part of their study could be explained on the basis of pure sympathetic stimulation. An intraneural connection between the fifth nerve

proper, the gasserian ganglion, and/or the somatic nerve to the levator is not necessary.

Further experimental work of theirs on the sympathetic nervous system was carried out, but this did not help to clear up anything. In some of their animals, simultaneously with the division of the oculomotor nerve, the ipsilateral cervical portion of the sympathetic trunk was resected for about one centimeter below the superior cervical ganglion. Subsequent injections of acetylcholine and atropine enlarged the palpebral fissure and the pupil as it did before cutting the cervical portion of the sympathetic trunk. Intravenous injection of from 5 to 10 mm. of ergotoxine increased the elevation of the upper lid, but no further dilatation of the palpebral fissure could be obtained by subsequent electrical stimulation of the gasserian ganglion or of the first division of the trigeminal nerve.

It seems possible, therefore, that in the first part of this study Cannon's law of denervation may be effective. In the second part, the same is probable, although more likely the effect is by way of the cervical sympathetic and the effects of stimulation to the sympathetic nervous-system supply for the unstriated muscles of the lid (Müller's orbito-palpebral muscle). The observations of Lewy, Grant, and Groff are undoubtedly correct and valuable. Their interpretation, however, is for the moment open to controversy, since it does not prove that the efferent pathway of the Marcus Gunn phenomenon is by way of the first division of the fifth nerve. One cannot be too certain of the role that this unstriated muscle of the upper lid may play. It might even be a major role in an associated reflex responsible for the Marcus Gunn phenomenon.

One wonders why the efferent portion of the arc of this Marcus Gunn syndrome

cannot be caused by congenital misdirection of developing peripheral (infranuclear) nerve fibers; the source of the fibers arising properly in the proper nuclei, the faulty distribution, however, occurring in the posterior longitudinal bundle or even more peripherally within the brain stem, excluding wholly any relationship to the autonomic system. The efferent pathway would then be by way of the superior branch of the third cranial nerve. This seems plausible when one considers the many vagaries of the pseudo-Graefe syndrome; as, for instance, the oddity of fibers destined for the inferior rectus terminating in the sphincter pupili. The sphincter pupili is certainly not a striped muscle. In the case presented, the fibers originally destined for the inferior rectus muscle formed subsequently the innervation of such a histologic type muscle.

The syndrome must have motor fibers as the efferent portion of the arc. The afferent portion of the arc may be purely proprioceptive, and it may arise even in connection with the higher cerebral centers. Similar higher cerebral center controlled phenomena are not uncommon. A feeble-minded individual examined recently developed a strong elevation of both upper lids through an emotional stimulation when chided, and Walsh⁵ has a patient in whom the lid elevated invariably whenever he lost his temper or became interested in an attractive member of the opposite sex. This certainly could be sympathetic in origin and not somatic in origin. One might, under such circumstances, consider the cortex as the point from which the synchronous action of this phenomena can be initiated.

Bender, however, as discussed by Walsh,⁵ had an experimental animal in which he obtained an elevation of the upper lid by producing rage in the animal, and this after sectioning of the third nerve. Bender concluded that it was sen-

sitivity to acetylcholine and not a sympathetic reaction. Cannon agreed with Walsh that Bender was probably correct as regards the elevation of the lid but that it was not proved completely. Upon this possibility, Walsh thought that the elevation of both lids, which occurred in his patient through emotional stimulation, was also the result of acetylcholine and not from sympathetic stimulation. Either might be the factor and this also might be proved experimentally.

Relative to this, two instances of a reverse jaw-winking associated reflex have been mentioned in the literature, one by Amat,⁶ and one by Benoit.⁷

The close proximity in the cerebral cortex of centers for the jaw and the eyelid is well-known. Adler⁸ suggested this as a possibility. Another consideration on this same basis is that of Wilson⁹ who spoke of such associated movements as an association of movements and not of muscles. We know, however, that in the Marcus Gunn phenomenon¹⁰ we are dealing only with a single muscle in the eyelid, and the experimental studies of Lewy, Grant, and Groff eliminate Wilson's and Adler's conjectures.

Embryologically the relationship between the motor nuclei of the fifth nerve and the nucleus of the oculomotor is rather close. The sensory root of the fifth nerve, which might constitute the afferent portion of the arc, arises separately from the motor root, and is a derivative, at least in part, of the ganglion crest. The motor root appears later than the sensory root and is derived from a mass of neuroblasts lying in close relationship to the developing oculomotor and trochlear nuclei in the floor of the mesencephalon. The neuroblasts, as they develop for both nuclei, third and fifth, belong to the lateral column. The motor root of the trigeminal nerve appears definitely later than does the sensory root. The ganglion itself has a

rather complex formation in that it is the fusion of proganglia and pronerves, several of each, into a complex mass. One can see, therefore, that it would be rather difficult, embryologically, for the development of intermingled sensory and motor fibers, as would be necessary if the first division of the gasserian ganglion was wholly the efferent portion of the arc. If, however, the entire reflex arc was a motor complex arising in the third division of the trigeminal, from thence to the gasserian ganglion, thereafter to the third-nerve nucleus by embryonal, intraneural connections (hence still motor) with the oculomotor nucleus and the pathologic efferent portion of the arc as a part of the oculomotor nerve, we see that it is embryologically and developmentally possible. These may not be conclusive ontogenetic explanations but they must be considered. Another possibility, mentioned above, is that the afferent pathway is sensory, but that in the gasserian ganglion the afferent pathway begins as motor, from there pathologically to the oculomotor nucleus and thence out by way of the third nerve to the levator. This seems to be suggested rather definitely in the first of the cases herein presented. In that case, as will be described, the levator palpebri superioris was the only muscle normally present and bilaterally so. All other ocular muscles and oculomotor nerves were absent. There was certainly a break in neural development of some type here, extraordinary in its character.

These pathologic associated reflexes, congenital or acquired, need not of necessity be a combination of proprioceptive afferent and motor efferent. As interesting is the sensory afferent and sympathetic efferent reflex arc which one sees in crocodile tears. This syndrome of crocodile tears, commonly considered as connected with facial paralysis alone, is actually not unlike the true Marcus Gunn

phenomenon except that the afferent and efferent pathways are a combination of sympathetic fibers (taste fibers), fifth-nerve fibers, and seventh-nerve fibers. The statement that this syndrome of crocodile tears is similar to the Marcus Gunn phenomenon is based upon the presentation of Lutman's¹¹ case in which he described two cases of facial asymmetry wherein a third-division, fifth-nerve, sensory stimulation resulted in a first division, sensory, response with lacrimation. In his cases the patients had (unilateral in one and bilateral in the other) congenital paralyses of the sixth nerve. This matter of crocodile tears as a pathologic associated reflex may be considered upon the following basis. Centripetally the taste fibers from the anterior two thirds of the tongue enter the facial nerve by way of the chorda tympani. From here the total possibilities are: (1) facial nerve fibers into the geniculate ganglion; (2) a new taste fiber into and through the superior (greater) superficial petrosal nerve; (3) sphenopalatine ganglion; (4) maxillary division of the fifth nerve and the gasserian ganglion; (5) nucleus solitarius of the medulla.

Lutman also thought that one had to consider seriously in his cases an intramedullary pathologic relationship between the sixth-nerve nucleus and the genu of the seventh nerve.

The suggestion had been made that this pathologic reflex, in its association, had misdirection of fibers in the sphenopalatine ganglion where they synapse about those cells whose axons go by way of the zygomatico-temporal nerve to connect with the lacrimal gland. This reflex arc does not need an intranuclear pathologically associated reflex according to the above opinion which first arose probably with Ford,¹² but it is possible.

Grant¹³ has made some very pertinent and important remarks relative to the

Marcus Gunn reflex. He asked the question: "Is there a nuclear connection in the brain stem?" And he answered the question as follows: "This was the opinion put forward by the commission that examined the patient in Gunn's original case." He himself (Grant) was unwilling to accept this answer.

Nuclear connections between the cranial nerves exist in the brain stem as exemplified by Bell's phenomenon, recently analyzed by Slotopolsky.¹⁴ The work of Mendel¹⁵ and Tooth and Turner¹⁶ and the clinical observations of Hughlings Jackson¹⁷ suggest a nuclear connection between the facial and oculomotor nerve; however, Harman¹⁸ vehemently denied, on morphologic and embryologic grounds, the possibility of any such internuclear connection, since they are of different orders of nuclei. Villard,¹⁹ Pontico,²⁰ and Amat⁶ discussed the possibility that the associated movements may in some way be mediated through the posterior longitudinal bundle. Lastly, the suggestion has been made that there may be peripheral connections between the branches of the third and those of the fifth nerve, although, as Pontico stated, detailed anatomic studies have failed to produce convincing evidence of this.

Walsh²¹ in a personal communication to me stated rather pertinently that this matter of congenital misdirection of developing fibers would have to be most seriously considered if a case would be found with seventh-nerve involvement present with the jaw-winking reflex. Case 3, to be presented, suggests an interesting possibility of congenital misdirection of fibers because the sixth nerve enters into the complex, and this could only be the result of brain-stem connections.

In presenting the first of the four cases of the Marcus Gunn phenomenon one can be certain that the onset of the phenomenon occurred very early in intrauterine

life, when the masses of orbital periaxial mesoderm should become differentiated into the oculomotor muscles. The failure of the development of these muscles may be ascribed to the failure of invagination of peripheralward developing (centrifugal) third-, and fourth-, and sixth-nerve motor fibers. Surgical exploration of this case showed, without any doubt, normal levators which must have been supplied by a portion of the oculomotor nerve, not sympathetic in nature. The other ocular muscles showed a pathologic condition. The degree of lid elevation was far greater than that possible by the unstriped muscles of the lid normally supplied by the sympathetic fibers, and the anatomic normalcy of the levators (seen surgically) seems to eliminate the possibility that the efferent pathway herein was sympathetic (autonomic) in nature.

Quoting Grant further: "Even if in the origin of congenital cases a pathway over which the synchronous movements are carried out could be worked out, the acquired type of associated movements could not be explained. Any presumption than an anomalous connection between the oculomotor and the other cranial nerves lies dormant waiting for the proper conditions to stir it into activity seems difficult to believe."

Stookey stated, in discussing Grant's¹³ original presentation, that since Grant's operation did not disturb an intra-axial internuclear connection between the motor nucleus of the fifth nerve and the nucleus of the third nerve, it was warranted, perhaps, in concluding that an intra-axial internuclear connection between these two motor nuclei did not play any role in the production of the syndrome. Stookey lost track of the fact that the afferent pathway can be proprioceptive and wholly sensory. As Grant said in concluding his presentation: "The most baffling part of the picture to me has been the fact that

the movement of the jaw has returned" (postoperatively in his patient) "but the movement of the eyelid does not accompany it."

In the case which Grant presented in his paper,¹³ he uncovered the gasserian ganglion through a temporal approach and sectioned the third division of the fifth nerve together with part of the ganglion that supplied the third division, trusting that by this maneuver he would cut the motor root as well. The patient had a very stormy recovery due to a secondary, postoperative, intracranial hemorrhage and temporary complete third- and seventh-nerve paralysis, but in a letter received by Grant one month after discharge from the hospital, the patient reported that he had no diplopia, no interference with vision, no recurrence of the associated movements, he had gained 20 pounds in weight, and the motor paralysis on the right side of the jaw in no way inconvenienced him.

The sensory afferent portion of the reflex arc is certainly granted. Equally certain is that the nerve pathways producing associated movement can be broken at either end. According to Grant, the afferent parts when injected (third division and motor root of the right fifth nerve) with procaine hydrochloride stopped the associated movement by preventing voluntary movement of the jaw to the left, and increased the ptosis of the right eyelid, making its voluntary elevation more difficult. It is conceivable that the injection reached the sympathetic fibers about the internal carotid artery, and hence increased the ptosis through the paralysis of the nonstriated fibers. It is significant (to this case of Grant's). Grant himself states: "However, in my experience the third division of the fifth nerve has been blocked many times with procaine, and this is the only incidence in which ptosis of the ipsilateral eyelid re-

sulted." (One must remember that the patient in Grant's case had primarily an established ptosis.) There are three possible reasons. The first has already been quoted, that is, the procaine injection might have reached the internal carotid sympathetic plexus, and increased the ptosis; second, the sympathetic fibers thus involved played an indefinite role in the complex efferent portion of the arc; and third, the somewhat later observation that the control of the afferent portion of the arc and its interruption by alcohol, did not increase the ptosis. Grant said in regard to this: "Since a much smaller amount of alcohol was used, little spread into the tissues occurred and the sympathetic fibers along the internal carotid were not affected." The intracranial surgery in Grant's case (exposure of the posterior two thirds of the ganglion and the sensory root with section of the third division and the motor root) could not have affected the sympathetic fibers along the carotid artery.

Of the four cases of jaw-winking to be presented, Case 1 developed his jaw-winking reflex with both the closure and the opening of the muscles of mastication, as well as with a side-to-side grinding movement. At the same time, this patient had a complete absence of movement of all the oculomotor muscles, except the sphincter iridis, the ciliary body (accommodation) and the two levators. There was certainly in this patient's case a congenital periaxial mesodermal nondevelopment of all of the oculomotor muscles which had to do with the movements of the eyeball, not including the normal iris sphincters. In view of the fact that only the levators functioned, they may be considered as part of the efferent portion of the arc of the Marcus Gunn phenomenon. Surgically, in this case, it was demonstrated that all of the extraocular muscles were present only as taut fibrous bands,

with the exception of the levator, but that the levators were perfectly normal, healthy muscle structures. When one considers the early intrauterine age at which the completed oculomotor third-nerve apparatus develops, it becomes evident that the period at which this syndrome formed, and was completed, was rather early in the growth of the fetus.

CASE REPORTS

*The first case*²² (figs. 2, 3, and 4) was that of a boy, aged 12 years, with bilateral ptosis of a high degree, with normal pupillary reflexes, with normal accommodation, and with both eyes directed strongly downward and to the left. Thus, the right eye appeared in downward and internal rotation, and the left eye in downward and external rotation. In this position of levoinfraduction, the visual axes were almost parallel horizontally, as well as vertically. The boy's visual acuity was not impaired when it was possible for him to use his visual axes for central vision. The lids lifted rather strongly with forcible closure of the jaws and even more so with a forcible hard opening of the jaws. Figures 2, 3, and 4 illustrate nicely the presence of the associated movements and the postoperative condition with prism glasses being worn.

The child was normal mentally, in fact, above average, but was very much handicapped by reason of his defect. The surgery for him was necessarily limited in that nothing could be done for the correction of the ptosis which would leave the cornea covered during sleep. Surgical exploration of his rectus muscles showed his strabismus fixus to be so marked that it was quite impossible to correct the hypotropia. A bilateral myectomy, therefore, was done of both levators, and the ptosis thus converted into a bilateral completely paralytic ptosis, now free of the jaw-winking associated reflex. Some time af-

ter this, a sufficient ptosis correction was obtained, by means of orbicularis transplants, so that the pupils were uncovered beneath the margin of the ptotic lids. The patient was then given prism spectacles for constant wear, bases up in both lenses

a most unfortunate and distressing neurosis, because of the conspicuous defect, and the curiosity of the unkind, though unintentional, comments of friends, adults, and other children.

This case was unilateral, on the right,

Fig. 2 (Spaeth). A, patient in repose with an almost complete ptosis. The orbito-palpebral fold is wholly missing. B, with the lids manually elevated, shows the bilateral hypotropia, somewhat dissimilar in degree, and with both eyes in partial left rotation. (Case 1).

permitting him to gaze directly to the front, though with his head still somewhat in a right-facing direction. The addition of two prisms, base to the right in the horizontal, corrected this right facing, but the amount of prism necessary made the spectacle lenses very heavy and conspicuous, and hence were not incorporated in the glasses. This patient has returned to school and is doing very well under his corrected conditions.

The second case was that of a girl, aged eight years, who had also had her condition since birth. This child was developing

developed only with the action of the pterygoids, did not appear with the action of the muscles which closed the jaw, and became very strongly accentuated when the patient looked downward while chewing.

Normally in downward gaze, the upper lid drops almost to the same level which it has with a normal closure of the palpebral fissure. Synchronous depression of the lower lid permits continued unimpeded downward vision. The elevation of the ptotic lid from this level of maximum depression is a third-nerve levator func-

tion and not a sympathetic-supplied, unstriped lid-muscle function and achievement. Later in this case, one could see that there was no doubt whatsoever of this. A myectomy of the levator muscle resulted in a complete cessation of the associated reflex. The sympathetic innervation of the

lower lid is a much less definite structure and not easily recognizable by dissection, it still is active in function and is innervated by the same group of sympathetic fibers related to the cervical sympathetic carotid cavernous sinus plexuses which supply the upper lid. The com-

Fig. 3 (Spaeth). Lids, upper, lifted in an associated reflex by strong closure of the jaw, A; and an even better elevation, B, by violent opening the lower jaw. Orbito-palpebral folds are very evident now and their position seems to be levator in origin, rather than autonomic. In A, the occipito-frontalis seems to assist in the elevation but this is not so in B. At this time the eyebrows are the lowest ever seen at any time, probably the only time relaxed. (Case 1).

non striped muscles of the lids, however, was not touched, but Müller's muscle itself, by reason of its position beneath the aponeurosis of the levator, was sectioned with the levator fibers. The reflex was stopped by sectioning the muscles innervated by a somatic and an autonomic nerve, each a possibly efferent pathway. While the orbito-palpebral muscle of the

plete lack of any pathologic condition in this associated reflex, before or after the myectomy, in the lower lid seems to suggest a greater significance for the somatic nerve supply.

*The third case*²³ was that of a 15-year-old girl, highly myopic. Although a moron, the patient had developed rather well into a third- or fourth-grade school

Fig. 4 (Spaeth). Case following surgical exploration of the oculomotor apparatus, following resection of the levators, and after orbicularis transplants for the ptosis. The patient is shown, as well, wearing his prism glasses. (Case 1).

level by the age of 15 years. There was a suggestion of bilateral obliquity of the palpebral fissures. The patient had a paresis of both external rectus muscles, a paralysis of the superior rectus on the right and a partial paralysis of the right inferior rectus muscle. There was a partial paralysis of the levator on the left, and a partial paralysis of the superior oblique on the left as well. *Both upper eyelids* entered into the jaw-winking re-

flex but it was most marked upon the left. As a result of her various oculomotor palsies, this girl had developed a spasm of the inferior oblique muscle upon the left and some overaction, relative at least, of the right inferior rectus muscle. (See figure 5 of the patient in repose.) Even more remarkable were other dissociations of the actions of the extraocular muscles. In downward gaze, the upper lids lagged definitely (fig. 6) behind the movement

Fig. 5 (Spaeth). In repose the patient shows nothing but a bit of ptosis in the upper lid (O.S.).

Fig. 6 (Spaeth). Elevation of both upper lids in downward rotation of the eyeballs, an intraneural, third-nerve, pathologic association.

Fig. 7 (Spaeth). Downward rotation to the left, a greater elevation now occurs in the left upper lid, showing the effect of the parietic external rectus on the left.

Fig. 8 (Spaeth). Downward rotation to the right. In this instance, there is a still stronger elevation of the right upper lid. The left lid remains unchanged.

Fig. 9 (Spaeth). Attempted right lateral rotation, now a demand only upon the right external rectus, results in the greatest amount of elevation of the upper lid. This shows an interneural third- and sixth-nerve association.

Fig. 10 (Spaeth). Left lateral rotations result in a bilateral elevation of the upper lids, more marked in the left, again an interneural as well as intraneural association, perhaps less conclusive than that seen in the right, Figure 9.

of the eyeballs. This was rather startling in appearance. In downward movement to the left, the right upper lid was lowered a bit more than on left (fig. 7). In attempted downward movement to the right, the right upper lid lifted very strongly while that on the left remained unchanged (fig. 8). The downward movements of the eyeball to the right were greatly limited. Right lateral rotations of both eyeballs to the right resulted in an even stronger elevation of the levator upon the right side (fig. 9). Rotations to the left caused similar but now bilateral elevations (fig. 10).

The fourth case is the most amazing of them all in a demonstration of intracranial-interneural relationships. The young man, B. J., aged 26 years, had had ptosis his entire life, and this was the reason for his initial examination. The

young man showed a classical jaw-winking reflex of the left upper lid, present with all chewing movements, closure as well as the lateral movements of the lower jaw. In repose, he had a complete paralysis of the upper lid, and with it a complete paralysis of the superior rectus muscle. In eyes front, fixing with the right eye, there were 40 degrees of left hypotropia. In the left lateral rotations, the patient developed 60 degrees of right hypertropia from the wild overaction of the right inferior oblique muscle.

The internal and inferior rectus muscles showed in their rotations normal amplitude. The action of the left inferior oblique muscle was greatly limited. In spite of the apparent complete paralysis of the superior division of the third nerve, the jaw-winking, associated reflex in the upper lid on the left was quite

active. In addition, however, in repose there was an almost constant asymmetric opening and closing of the upper lid, greatest in amount when the patient was animatedly engaged in conversation upon some subject other than his eyes. The movements of this lid were wholly separate from those normal movements in the right upper lid. Frequently, there was quite a see-saw action of these two lids; that is, a normal blinking closure of the right upper lid was simultaneous with a rather wide opening movement of the left upper lid.

Demand for movement in the paralytic superior rectus muscle (upward gaze) minimized to a great extent these movements of the upper lid, although some still continued. A demand for the use of the paretic inferior oblique muscle did not modify them in any way whatsoever. In this case the upper lid was completely paralyzed to all voluntary movements; nevertheless, there was a constant action of the upper lid, not sympathetic in origin (autonomic nerve supply), and this was inhibited rather definitely in upward gaze—now a demand upon the paretic superior division of the oculomotor nerve.

These movements occurred rather asymmetrically, although constantly. The lid movements which developed with chewing were rhythmic and synchronous with the motions of the lower jaw.

Acetylcholine stimulation cannot be the answer to this disorder. The jaw-winking association is only a part of the condition as seen. The condition is not the result of cervical-sympathetic stimulation, neither normal in degree nor in relative overstimulation because of the levator paralysis, and these lid movements were definitely inhibited by attempted upward gaze even though the eye did not and could not move upward.

From these pathologically associated

movements one can see that binocular stimulation, when downward movements are demanded, results in some elevation (retarded depression) of the upper lids. When demands in addition are made upon either of the paretic external rectus muscles, a very strong additional elevation occurs in the lids; namely, the levators. The first of these situations can be a misdirection of a portion of the third-nerve inferior rectus muscle fibers into the levator fibers, fibers destined for the inferior division of the third nerve terminating in the superior division. This might well be a confusion occurring within the trunk of the third nerve itself. When lateral rotations are demanded (in the second situation of these two), however, the associated ocular-muscle reflex can be answered only upon the basis of excess acetylcholine formation, through emotional (cerebral) stimulation, by sympathetic stimulation, or because those fibers which should have terminated in the external rectus muscles have found their way, in some bizarre association, with the third-nerve nuclei or the third-nerve intranuclear tracts. This association could hardly be outside the brain stem. The pathologically associated jaw-winking reflex in this case was present bilaterally but much more marked upon the left side. The case, therefore, appears to be a congenital type of an internuclear syndrome involving the third nerves, the motor divisions of the fifth, the sensory divisions of the fifth, and the sixth nerve (the cranial nerves bilaterally), of dissimilar degrees, however, and associated with other manifestations of higher cerebral disturbances.

The analysis of a case of the acquired form of these faulty intraneural associations connected with regeneration of oculomotor-nerve fibers, that is the pseudo-Graefe syndrome, is significant to these congenital forms of malassociation.

In Case 1, herein presented, the patient had a paralytic levator, a paralytic superioris rectus, and a paretic inferior rectus and inferior oblique, and an internal ophthalmoplegia. The internal rectus showed some return of function. The pupil was widely dilated and fixed. (Normally the third-nerve fibers to the sphincter iridis pass to the iris by way of the branch of the third nerve to the inferior oblique muscle.) In this case when maximum regeneration had occurred in the third-nerve trunk, fibers destined for the internal rectus found their way into the levator, in that, with contralateral rotations, the lid lifted. When downward rotation was called upon, that is, the functioning of the incompletely paralyzed inferior rectus, the pupil contracted; hence, fibers which terminated in the sphincter iridis had been destined for the inferior rectus muscle, and in some way had passed to the ciliary ganglion and to the sphincter iridis. There was no inferior oblique, levator, nor superior rectus regeneration whatsoever; hence the direct or reestablished peripheral connection is uncertain.

This confusion of terminal fibers occurred infranuclearly from some point in the trunk. The traumatism responsible for the initial third paralysis was intracranial and at the base. Considering the contralateral hemiplegia (hemiplegia alternans superioris) which the patient had at that time, the third-nerve paralysis was a part of an interpeduncular syndrome. The important question here is "at what point did the regeneration begin?" Certainly before the third nerve split into its two major intraorbital branches. The fact that internal rectus fibers passed through to the levator is evidence of this.

Another interesting speculation in regard to this case is to hazard a guess as to why there was such extensive regeneration of the internal rectus fibers

and the sphincter fibers; partial regeneration of the inferior rectus fibers; and no regeneration whatsoever of the true fibers for the levator, superior rectus, and the inferior oblique muscles. The nerves to these muscles have their terminal distribution in both the superior and the inferior major orbital terminations. This seems to suggest that regeneration of the third-nerve fibers might have started considerably higher in the course of the third-nerve trunk than even the interpeduncular space.

The successful surgery in this case inspired the surgery for the Marcus Gunn phenomenon. The gross paralytic oculomotor defect was first corrected because of the paralytic divergent squint (recession of the external rectus with resection of the internus). The pseudo-Graefe syndrome was then changed to a completely paralytic form of ptosis by a thorough myectomy of the levator including the two lateral horns. This paralytic ptosis was then subsequently corrected by a Reese orbicularis transplant.

The surgery carried out for the pseudo-Graefe syndrome was applied as satisfactorily to cases with the Marcus Gunn phenomenon. In Grant's case, the afferent proprioceptive pathway was sectioned intracranially, in the oculomotor extracranial surgery the efferent motor path is destroyed and the subsequent defect corrected by means already well-known. It is a logical procedure and without the dangers and complications attendant to that seen in Grant's presentation.

The surgery in Case 3, herein presented, was decidedly simplified in that the paralytic ptosis which occurred following the myectomy of the levator on the right side could be fully corrected by orbicularis transplants without any limitations in surgery, since there were no other disturbances with the remaining ocular muscles.

CONCLUSIONS

The underlying pathology of the Marcus Gunn phenomenon has been discussed, in part, with the consideration of the theories which have seemed plausible, although without a satisfactory conclusive solution.

There is a possibility that some of the cases of these pathologic associated reflexes might be the result of an afferent proprioceptive reflex pathway and a sympathetic (autonomic) efferent pathway as seen experimentally.

It is certain that other cases may appear with brain-stem internuclear, pathologic, anatomic connections as the cause of the associated reflex.

It is probable that other cases of associated reflexes have an origin in supranuclear higher cerebral centers, for emotional stimulation plays an indefinite but likely role. Of the three cases presented, the first demonstrated the very early development of the pathologically associated reflex in terms of intrauterine life.

Case 2 showed no pathologic condition whatsoever except a unilateral pathologic associated reflex and demonstrated a lack of any certain autonomic relationship. Sectioning the efferent pathway, that is the muscle supplied by a somatic nerve, abolished the reflex.

Case 3 showed a gross bilateral nuclear and tract pathologic condition involving

the third, fourth, fifth, and the sixth cranial nerves, all with varying degrees of unilateral and bilateral paralyses. One portion of the associated reflexes here had its afferent origin in the muscle supply of the pterygoids. Another portion arose in the brain stem and was associated with the innervation called upon for right and left gaze. A third portion was apparently a peripheral misdirection of the third-nerve fibers.

Case 4 is similar to Case 3 in some points. It shows a dual cause for the jaw-winking reflex, one separate from the other; one is associated as a reflex, but the other is rather certainly a pure central-nuclear or supranuclear condition. This demonstrated something akin to an inhibitional palsy; that is, inhibition of the reflex with central stimulation for upward gaze. It seems that this case presents a very strong brief for the likelihood that the condition could be a brain-stem, intranuclear syndrome.

Cannon's law of denervation and its relationship to acetylcholine was considered and discussed in relationship with the previous work of Grant, Groff, and Lewy.

Surgery, as an ophthalmic procedure, is stressed, as indicated, for the condition. An intracranial approach, it appears, is not necessary for the correction of these cases.

GONIOSCOPY*

ERNEST A. W. SHEPPARD, M.D., AND WALTER J. ROMEJKO, M.D.
Washington, D.C.

The purpose of this communication is to present a simple technique of low magnification gonioscopy and to show the findings of the examinations made by this method. The instruments that have been designed for gonioscopy have high magnification which is associated with restricted depth of focus. They are also somewhat heavy, which, for the beginner who takes longer to make the examination, causes fatigue. With the lower magnification, the beginner more easily orients the landmarks of the angle. For these reasons, the method is presented for the beginner; it is not intended to replace the examination made with higher magnification. Inasmuch as the technique is simple and the equipment inexpensive, it would seem it should be added to the diagnostic armamentarium of the ophthalmologist. Its continued use has shown that it is not just another examination and a passing fancy.

The examination is made with the goniolens as described by Troncoso.¹ The eye is anesthetized with pontocaine and the upper edge of the lens inserted under the margin of the upper lid while the patient looks down. The lower edge of the lens is inserted under the margin of the lower lid while the patient looks up. When the interpalpebral fissure is large or the lid muscles relaxed, it may be necessary to hold the lens on the eye with slight pressure of a cotton applicator or with the rubber suction nipple used to hold the lens while inserting it. For small interpalpebral fissures and for patients with pronounced blepharospasm, a smaller size

goniolens is advisable. After insertion of the lens, the space between the lens and the cornea is filled with saline solution. The presence of bubbles interferes with the examination and they must be removed. No injury has resulted from the examination except when the goniolens was left on unduly long; this resulted in

Fig. 1 (Sheppard and Romejko). Technique of low-magnification gonioscopy. (Photograph by courtesy of the Variety Club of Washington, D.C.).

slight discomfort only. The examination of the angle is made by using the ordinary loupe and the illumination of the ophthalmoscope from which the head, but not the condensing lens, has been removed.

In learning the technique and orientation, it is preferable to start with normal eyes and with eyes which have deep anterior chambers. As one becomes more adept in the examination, it can be used in cases of glaucoma in which it serves, not to make a diagnosis, but to differentiate

the wide- and narrow-angle types. Its value in surgery, preoperatively and post-operatively, has been given by Troncosco,² Sugar,³ Troncoso and Reese,⁴ and Meyer

it is impossible to "see over the hump." (Kronfeld⁸). Usually a small darker band can be seen—the ciliary portion of the iris. Beyond this may be seen the fine strands of the pectinate ligament, like fine spider webs. The trabecular spaces are identified by a more or less pigmented dotted line. Above this is the corneal endothelium underlying the limbus (fig. 2).

and Sternberg.⁵ While its major indication is in glaucoma, Moreu⁶ lists 11 groups of cases which he has studied by means of gonioscopy. These groups include congenital, traumatic, and inflammatory conditions; conditions caused by malnutrition, atrophy, anterior synechia, tumors and pseudotumors, and glaucoma; as well as conditions occurring after iridectomy, postoperatively and in fundus disease. Sugar⁷ gives cases other than glaucoma in which its use is indicated; namely, anomalies, hydrophthalmos, congenital megalocornea, congenital coloboma, aniridia, tumors, cysts, tuberculosis, trauma, and inflammatory lesions.

CASE REPORTS

GROUP I (NORMAL)

In making the examination one starts at the pupillary border of the iris and follows it back to the "last roll of the iris." Sometimes this roll is so pronounced that

GROUP II (TRAUMATIC)

Case A. D. C., a man aged 49 years, was a grocer. On September 11, 1944, his right eye was injured when a beer bottle exploded. There was a laceration of the cornea, just within the limbus at the 12-o'clock position through which the iris had prolapsed. An iridectomy was done, followed by a conjunctival flap. Figure 3 shows the edges of the iris caught in the

Fig. 3 (Sheppard and Romejko). The edges of the iris caught in the wound. 1, peripheral incarceration of iris pillars in wound. 2, dialysis of ciliary body. 3, ciliary processes. 4, edge of lens.

wound, traumatic ciliary-body dialysis, and the normal ciliary processes. At the last examination on July 25, 1945, the eye was quiet and corrected vision was 20/15—1.

Case B. L. K. C., a woman aged 28 years, was in an automobile accident on January 8, 1945, and suffered a laceration of the cornea of the left eye with prolapse of the iris at the 6-o'clock position. An iridectomy was performed, followed by a conjunctival flap. Figure 4 shows the peripheral incarceration of the iris in the wound. Resulting vision was $20/20\pm$, unimproved with glasses due to a slight central nebula of the cornea.

Case C. A. S. J., a woman aged 28 years, had both eyes injured in a powder explosion on July 1, 1944. Examination

Fig. 4 (Sheppard and Romejko). 1, iridectomy with peripheral incarceration of the pillars of the iris.

was made on March 15, 1945. Vision was $20/30$ in the right eye; $4/200$ in the left. This reduction in vision was attributed to traumatic central choroiditis in each eye as well as to changes in the posterior capsule of the left lens. Gonioscopic examination of the left eye showed peripheral anterior synechiae, iritis deposits on the corneal endothelium in the angle similar to the iritic deposits on the anterior capsule of the lens following the breaking up of posterior synechiae, and dialysis of the ciliary body. In the area

Fig. 5 (Sheppard and Romejko). An eye injured in a powder explosion. 1, remnants of peripheral synechiae in angle. 2, peripheral anterior synechiae. 3, partial dialysis of the ciliary portion of the iris. 4, atrophic portion of the iris.

of this dialysis, the under surface of the sclera was dotted with pigment. The iris in the area corresponding to the dialysis was atrophic (fig. 5).

Case D. B. C., a man aged 24 years, was injured in the right eye on April 11, 1945. A foreign body was removed by magnet

Fig. 6 (Sheppard and Romejko). An eye injured by a foreign body. 1, trabecular spaces. 2, partial dialysis of ciliary body. 3, laceration of iris.

Fig. 7 (Sheppard and Romejko). Without gonioscopic examination, the foreign body in the angle would have been missed. 1, foreign body in the angle behind the limbus. 2, foreign bodies on the iris.

on April 16, 1945. Gonioscopic examination showed a slight dialysis of the ciliary body, a deep angle, and a hole in the iris (fig. 6).

Case E. K. B., a man, aged 19 years, was injured in both eyes when a dynamite cap exploded in April, 1944. Examination on July 26, 1945, showed vision to be: O.D., 20/200, with a + 8.00D. sph. \ominus +2.75D. cyl. ax. 160°; O.S., 20/15-2, with a +10.75D. \ominus sph. \ominus +1.00D. cyl. ax. 75°. The reduced visual acuity in the right eye was due to a traumatic cataract. There was also a detached retina of the right eye. X-ray studies showed the shadow of a foreign body in the right eye. In the left eye, there were several foreign bodies on the iris and one in the angle. These were too small to be demonstrated by X ray. Without gonioscopic examination, the foreign body in the angle would have been missed (fig. 7).

GROUP III (GLAUCOMA)

Case A. Wide angle glaucoma simplex of the pigmentary type. W. L. C., a

woman, aged 43 years, was examined on October 22, 1943. Corrected vision was 20/20-1 in the right eye; 20/20+3 in the left eye. There was cupping of the discs, more so of the right. Tension was: O.D., 40 mm. Hg (Schiotz); O.S., 25 mm. Treatment started with ¼-percent pilocarpine nitrate, four times a day, which was gradually increased to 4-percent pilocarpine, four times a day. Iridencleisis of the right eye was done on January 9, 1945, and of the left eye on December 11, 1945. The tension on January 25, 1946, was 17 mm. in the right eye; and 13 mm. in the left eye. Gonioscopic examination showed the trabecular spaces so filled with pigment that the appearance was one of a straight black line (fig. 8).

Case B. Secondary glaucoma. Uveitis of undetermined origin. M. D. F., a woman, aged 71 years, had an attack of acute glaucoma in the right eye on March 16, 1944. Tension was O.D., 80 mm. Hg (Schiotz); O.S., 25 mm. The tension of the right eye was reduced to 40 mm. by myotics and on March 20, 1944, an iridencleisis was done. Preoperatively, there was no slitlamp evidence of uveitis in either eye. By mistake atropine was used

Fig. 8 (Sheppard and Romejko). Wide angle glaucoma simplex of the pigmentary type. 1, trabecular spaces blocked with pigment.

in the unoperated left eye and this revealed an irregular pupil, due to posterior synechiae. Gonioscopy of the left eye showed three marked peripheral anterior synechiae and deposits on the lens and on the corneal endothelium. Tension in the left eye has been fairly well-controlled by repeated paracenteses. The outcome of the right eye has been unsatisfactory due to uveitis (fig. 9).

Case C. Secondary glaucoma. Uveitis of asymptomatic malarial or tuberculous origin. L. B., a woman, aged 25 years,

Fig. 9 (Sheppard and Romejko). Gonioscopic picture of an eye with secondary glaucoma and uveitis of undetermined origin. 1, deposits on the corneal endothelium. 2, anterior peripheral synechiae. 3, trabecular spaces. 4, ciliary-body band. 5, iritic deposits on the anterior surface of the lens.

was seen on January 30, 1941, when the left eye had deposits on the corneal endothelium and tension was 22 mm. Hg (Schiøtz). On March 6, 1941, the tension had increased to 32 mm. but dropped to 17 mm. the following day. The tension has fluctuated with repeated attacks. Paracentesis was done on April 17, 1945. Gonioscopy showed a large peripheral anterior synechia with occasional openings. The pectinate ligament was more pronounced than normal and at first sug-

Fig. 10 (Sheppard and Romejko). Gonioscopy showed a large peripheral anterior synechia with occasional openings. 1, pectinate ligament extending from the root of the iris to the upper border of the trabecular spaces. 2, in two places the ciliary portion of the iris can be seen. 3, a few pigment spots on the iris.

gested newly formed fibrous tissue (fig. 10).

*Case D. Leiomyoma of the iris.*⁹ M. L., a 27-year-old woman, had had a brown spot in the inferior temporal part of the right iris for as long as she could remem-

Fig. 11 (Sheppard and Romejko). Gonioscopy showed the root of the cut iris and the ciliary processes. 1, iridectomy for leiomyoma of the iris. 2, corneal and lenticular haze due to pressure of the tumor.

ber. Iridectomy was performed on January 5, 1943. Gonioscopy showed the root of the cut iris and the ciliary processes. At the last examination on January 31, 1946, there had been no recurrence of the tumor. The corneal endothelium upon which the tumor pressed has very gradually become less transparent. This very slight and slow increase in loss of transparency has not extended beyond the original area of pressure. The corneal epithelium in the corresponding area has begun to show evidence of edema (fig. 11).

In making the gonioscopic examinations, two cases of iridodonesis have been unexpectedly found. The tremor of the iris is magnified and much more easily seen when looking in the plane of the iris than when looking at right angles to it. One patient had a cataract, the operation of which was undertaken with greater con-

fidence because to be forewarned was to be forearmed.

CONCLUSIONS

1. A simple technique of low-magnification gonioscopy is presented.
2. The method is of value to the beginner because of the greater ease in orientation.
3. The indications for gonioscopy are not limited to glaucoma but it should be a routine examination in glaucoma and in intraocular surgery both preoperatively and postoperatively.
4. Iridodonesis is magnified by this method of examination and is therefore more easily diagnosed.

We wish to thank Miss Lorraine Bean for the assistance she has given in the making of the examinations, for the illustrations, and for the helpful interest she has shown.

POSTNEURITIC OPTIC ATROPHY IN REPATRIATED PRISONERS OF WAR

WALTER L. ROBERTS, M.D., AND LIEUT. T. H. WILLCOCKSON, (MC), U.S.N.
Los Angeles, California

During the war years, there were many reports of visual disturbances in individuals who were forced to live under inadequate dietary conditions.¹⁻⁴ We have had an opportunity to study such disturbances in men returned from Japanese prison camps. The incidence of permanent visual impairment was alarming and has been confirmed in many Army and Navy hospitals.

Reviewing publications of the past decade concerning nutritional diseases in which vision failure was an outstanding symptom, we find many convincing reports. Krylov⁵ described 36 cases of pellagra in natives of the Caucasian mountains with accompanying optic-nerve pathosis. He observed paleness of the nerve head with scotomas for red and green.

Moore^{6, 7} described a common disease in adolescent school boys in which loss of central acuity of vision associated with sore tongue and mouth were predominant features. Avitaminosis was suspected as the causative factor, because girls, who received supplementary feedings at school, appeared immune to the disease. A number of the patients were treated with cod-liver oil, malt, marmith, and iron with successful results. Moore concludes that the prognosis for the return of vision in cases of less than six months' duration was excellent, but if the duration were over six months, the prognosis must be guarded.

Moore⁸ also described a syndrome of glossitis, stomatosis, pruritis of the external genitals, and dimness of vision with loss of central acuity. School children were particularly affected. In the

author's opinion, based on the observation of some 300 cases, the disease was caused by the use of "gare," a common and cheap food, with inadequate supplementary food.

Other reports, notably those of Levine,⁹ of Fine and Lachman,¹⁰ Ramon and Abbu,¹¹ and Verma,¹² point conclusively to the part avitaminosis can play in the production of optic neuritis.

Probably the most complete recent study made on this subject was that of Spillane and Scott.¹ They described a peculiar neurologic syndrome consisting of retrobulbar neuritis, nerve deafness, and ataxic paraplegia in 112 prisoners of war. The majority of these cases came from one camp. A nutritional neuropathy seemed the most probable explanation of the illness, since there was no evidence of poisoning, infection, or other cause. Peraita,² Wilkinson and King,³ and Whitacre,¹³ all describe similar syndromes in people living under war conditions. Although these described changes are thought to be nutritional in origin, the response to vitamin therapy has not been very satisfactory.

A brief summary of six representative cases which we have been told are typical of those seen at other military hospitals will follow. It should be emphasized that we saw all these patients from two to three years after the original visual symptoms developed and that we are observing the terminal effects of the nutritional neuropathy. We had to rely entirely upon the history from the patients as to when the visual impairment started; what treatment, if any, was given; whether or not other nutritional syndromes, such as def-

inite beriberi and pellagra, were present. We are presenting these cases as a contribution to the number of similar, previously reported cases, hoping to emphasize the importance of an adequate diet especially for people living under war conditions and to point out the marked visual incapacitation that can result from neglect to supply such a diet.

CASE REPORTS

Case 1. J. M. B., PI/Sgt. U.S.M.C., aged 45 years, was captured at Wake Island on December 23, 1941. He was confined in two camps in China and two camps in Japan. He first noticed blurred vision in September, 1942. This blurring increased gradually until January, 1943. Since that time, he feels that there has been no change in his vision. He stated that he had had no specific nutritional disease but suffered from severe malnutrition and lost considerable weight (the exact amount was not known). He received some cod-liver oil and vitamin-C tablets intermittently with no improvement in his vision.

Ocular examination at this hospital, three years after the onset of symptoms, showed vision in each eye to be 2/20, unimprovable. The media were clear, and the fundi showed the disc margins to be indistinct with slight temporal pallor. Perimetric examinations revealed the peripheral fields to be normal. The central fields showed bilateral, absolute, central scotomas of around five degrees.

Case 2. J. D. S., Sgt., U.S.M.C., aged 25 years, was captured on Corregidor, May 6, 1942. He was confined in two camps in the Philippines and one in Japan.

He first began to notice visual impairment in January, 1943. At this time, his diet consisted of boiled rice, potatoes, and occasionally meat. He received some vitamins and eye drops about six months after his vision began to fail. There was some

improvement in vision for a period of about three months. He soon noticed a return of the blurred vision, however, and there was no change during the last 20 months of his internment. He suffered from pellagra, beriberi, and diarrhea while he was a prisoner.

Upon examination at this hospital three years after the onset of symptoms, vision in each eye was found to be 2/20, unimprovable. Funduscopy examination showed a temporal pallor of the disc in each eye, with a granular appearance of both maculas. Perimetric examination revealed bilateral, absolute, central scotomas. The peripheral fields were normal.

Case 3. I. C. S., S/Sgt. U.S.M.C., aged 24 years, was captured on Bataan, on April 9, 1942. He was confined in three Philippine prisons and one in Japan. He first noticed impairment in his vision in April, 1943. At that time his diet consisted of rice and thin green soup and, occasionally, meat. He was given vitamin A in small quantities for his eye symptoms, with slight improvement. His vision gradually failed the last year of his confinement and has remained stationary since then. He had "wet beriberi" at the onset of his visual loss.

Upon examination in this hospital, three years after the onset of his symptoms, vision in each eye was found to be 2/20, unimprovable. Funduscopy examination of each eye revealed temporal pallor of both optic discs. The macula in each eye was granular in appearance, and the light reflex was absent. Perimetric examination of both eyes revealed absolute central and paracentral scotomas, with normal peripheral fields.

Case 4. K. K. K., PI/Sgt. U.S.M.C., aged 35 years, was captured on December 23, 1941, on Wake Island. He was imprisoned in several camps in China and Japan. He first noticed blurring of his vision in August, 1942. At that time he

was eating small quantities of rice, stew, watery fish stew, and, occasionally, vegetables. He believed he received ascorbic-acid injections for 44 days in 1942. In 1943 and 1944, he received nine vitamin pills daily for a total of 45 days. He stated that there was improvement of his vision on this therapy. When it was discontinued, however, the improvement was not sustained. He had had beriberi, pellagra, and malnutrition, with a weight loss of 37 pounds.

Examination at this hospital 3½ years after the onset of the loss of vision, revealed the vision in each eye to be 10/20, unimprovable. Funduscopy examination of each eye revealed slight temporal pallor of the optic discs and granular maculas, with absent light reflexes. Perimetric examination showed absolute central scotomas bilaterally, and a contracted, left peripheral field.

Case 5. H. M. E., Pfc. U.S.M.C., aged 31 years, was captured on Corregidor, May 6, 1942. He was confined in three camps in the Philippines and one in Japan. His vision first became impaired in November, 1942, at which time he had had corneal ulcers. At the time of onset of symptoms, his diet consisted of rice and vegetable soup in small quantities. After the onset of symptoms, he was given one tablespoon of cod-liver oil a day for two months, plus one vitamin-A pill a day for two weeks. He stated that his ulcers healed in three months but that his vision never did clear. He had beriberi in 1943.

Examination at this hospital, four years after the onset of the visual symptoms, showed this patient to have corneal opacities in both eyes. Vision in the right eye was 2/20, improvable with homatropine dilatation to 6/20. Vision in the left eye was 6/20, improvable to 8/20, with homatropine dilatation and a -1.25 sphere. Slitlamp examination revealed

central corneal opacities of both eyes, but the periphery of each cornea was clear. Funduscopy examination revealed slight temporal pallor of the optic discs. Perimetric examination showed some constriction of the right peripheral field with normal central fields. An optical iridectomy of the right eye was done, with visual improvement to 6/20.

Case 6. J. B. G., BMLC U.S.N., aged 26 years, was captured on Corregidor, May 8, 1942. He was imprisoned in several camps in Japan. In September, 1942, he began to complain of a sore tongue and blurred vision. At that time, he also noticed some heaviness and weakness of his legs. In spite of these complaints, he was forced to do heavy physical work. Two months later he complained of severe shooting pains in his legs, became suddenly paraplegic, and lost control of his sphincters. He was diagnosed as having beriberi and was immediately transferred to Japan. At this time, he stated, he was almost blind. Six months after his arrival in Japan, he developed a corneal ulcer in his left eye. This cleared up after a long period of convalescence. Beginning in the spring of 1943, there was a gradual improvement in all of his symptoms for a period of six months. Since the fall of 1943, there has been little change in his condition. He was hospitalized continuously until his liberation and, during that period, he lost 110 pounds in weight.

Examination at this hospital, 3½ years after the onset of his symptoms, revealed vision in the right eye to be 5/20; and in the left eye 1/20, unimprovable. Slitlamp examination revealed a large, central scar of the left cornea, with an anterior synechia of the nasal pupillary portion of the iris to the scar. The left lens showed some anterior-capsular opacities. Both fundi were seen and appeared normal. Perimetric examination revealed constriction of both peripheral fields, more

marked in the right eye. The left eye showed an absolute central scotoma, and the right eye an absolute paracentral scotoma.

DISCUSSION

The existence of food-deficiency diseases in these cases was undeniable. All of these patients, except one, gave histories of having suffered from beriberi or pellagra, and all had suffered severe malnutrition, with marked loss in weight.

There has been some controversy as to which vitamin deficiency was responsible for this type of optic-nerve degeneration. Mellonby¹⁴ showed that vitamin-A deficiency in dogs was associated with severe degeneration of the afferent nerves, including the optic nerve. Rao¹⁵ observed myelin degeneration in the optic nerve of rabbits, rats, and fowls fed on diets lacking in vitamin A. Vitamin-B₁ deficiency has long been associated with retrobulbar neuritis and optic-nerve degeneration. Rea,¹⁶ Ramon and Abbu,¹¹ and Landor and Pallister¹⁷ reported cases of optic-nerve degeneration in a vitamin-B₂ deficiency syndrome. A large group of patients from the Japanese prison camps were carefully studied by McDaniel and others.¹⁸ The clinical findings for these patients indicated definite deficiency in the vitamin-B complex, extrinsic factor, and protein.

The fundusoscopic appearance of the cases herein reported was fairly uniform. All but one case showed slight temporal pallor of the discs; foveal light reflexes were absent; and the maculas had a granular appearance. Visual acuity varied from 1/20 to 10/20. The visual fields were recorded on a perimeter and Bjerrum screen at one meter. The peripheral

fields were constricted in only two cases; and all but one case showed bilateral absolute central or paracentral scotomas. These findings are similar to those described by other observers.

All these patients were given intensive dietary therapy upon liberation. McDaniel and others¹⁸ described the dietary management of the repatriates, and it is reasonable to assume that this regime was fairly well standardized. Ninety percent of the men were given six full meals a day, in addition to ice cream and chocolate bars. It was estimated that a 5,000-calorie diet was given, supplemented with the following vitamin intake:

Vitamin A	15,000 units
Vitamin B ₁ (thiamin)	20 mg.
Vitamin B ₂ (riboflavin)	10 mg.
(niacinamide)	60 mg.
Vitamin C (ascorbic acid)	225 mg.
Vitamin D	1,200 units

In no case, as determined by the visual examinations on repatriation, did the visual examinations during this therapeutic regime show any change. This tends to substantiate Moore's⁶ observation that the prognosis of the return of vision in cases of longer than six months' duration must be guarded.

SUMMARY

Since the return of personnel from the Japanese prisoner-of-war camps, most ophthalmologists in Army and Navy hospitals have seen permanent visual impairment which in all probability is nutritional in origin.

We have presented six typical cases of severe ocular disability the onset of which was concomitant with marked dietary deprivation.

NUTRITIONAL RETROBULBAR NEURITIS IN CHILDREN IN JAMAICA

DAHLIA WHITBOURNE, M.B.*
Kingston, Jamaica, B.W.I.

Dimness of vision associated with impaired hearing was mentioned by H. H. Strachan¹ in accounts of peripheral neuritis in Jamaica in 1888 and 1897. This condition occurred in adults as well as children. H. H. Scott,¹ in 1917, described a disease which he called the central neuritis of Jamaica. He described impaired vision and hearing, itching and burning of the eyes, photophobia, inflammatory lesions in the mouth, fissures, and salivation. In 1927, E. Jenner Wright² described a new deficiency disease, the A-B avitaminosis of Sierra Leone. In Jamaica, faulty vision due to optic-nerve lesions has been commonly complained of by adults. Inasmuch as many of these patients have had positive Wassermann or Kahn tests, the condition in some cases has been ascribed by physicians to yaws or syphilis. In 1934, during a post-hurricane period of food shortage, there was an epidemic of cases of nutritional edema and "dark eyes" among children. These came under the care of Drs. L. M. Clark and W. N. Dickenson at the Kingston Public Hospital. The cases responded so

well to cod-liver oil plus a liberal diet that these doctors published an article on this subject in 1936.³ As far as is known, neither of these men was aware of similar diseases in Africa.

As school medical officer of Kingston, I treated several hundred similar cases more or less successfully with a mixture of cod-liver oil and iron plus a diet of protective foods for four years from 1934 to 1938. At that time my attention was drawn to E. Jenner Wright's² article and Fitzgerald Moore's description⁴ of pellagra in West Africa. The substitution of dried brewers yeast for cod-liver oil was effective in nearly all cases, although some cases seemed to require both products for restoration of satisfactory vision (6/6 or 6/9). The view was, therefore, taken that deficiency of no one vitamin was responsible, but that both vitamins A and B were implicated.

ANALYSIS OF THE CASES

The following are observations on 74 cases of retrobulbar neuritis treated at the School Clinic in Kingston during the year 1945.

* School Medical Officer.

Race, Sex, Age. The children were all colored or black. (In Jamaica "colored" means of mixed European and African blood; "black" indicates a more or less pure-blooded African.) Girls outnumbered boys roughly in the ratio of 2 to 1. The youngest child was 9 years of age, the oldest, 16 years; the majority were in the 12- to 13-year-old age-group.

Residence. All the patients, except two, came from urban areas in spite of the fact that rural children are usually more poorly nourished than town dwellers and often show marked signs of vitamin-B deficiency. Angular stomatitis and glossitis were often present, skins were overly dry and exhibited uneven pigmentation. The skin in some cases was also thickened and cracked. Many children appeared to be in fairly good condition, however.

These children came from the poorer social-economic groups in the majority of cases. Children and parents alike were unobservant, often ignorant. In the higher economic groups the visual defect was noted earlier.

Symptoms. A history is usually difficult to obtain. Unless discovered by routine school examination, cases are not usually seen until far advanced, at which time vision is 6/24 to 6/60, or less. The children make no complaints other than "dark eyes," not being able to see the blackboard, or print running together. They seldom give any account of the time of onset of special symptoms. The patients never complain of pain but occasionally mention photophobia.

There may be signs of general malnutrition, or there may be nothing but over-red lips, particularly noticeable with dark skins. Pèrleche and varying degrees of glossitis may be present. Occasionally the muco-cutaneous junctions of the eyes and nostrils are affected.

Deafness is the most serious concomitant sign. This condition was very evident

in 10 cases and could, no doubt, have been found in more if tests had been made. In contradistinction to Scott's¹ cases of peripheral neuritis there was only one case of ataxia and no complaints of sensory changes.

Visual Examination. The ocular and palpebral conjunctivas are sometimes congested, but usually appear normal. Pupilary reactions are usually slow. Vision varies from 6/9 (J2) to 2/60 (J14). The refraction is usually emmetropic or slightly hypermetropic. In the 74 cases reviewed here, no case exceeded a +2.50 in hypermetropia, and there were only three myopes. This illustrates the low incidence of refractive errors among school children in Kingston.

Dr. Frank D. Carroll demonstrated central scotomas in numerous cases he tested on his visit to Jamaica (see page 172). Color vision is impaired in many cases. This can be found only on testing, for patients never complain of this. The fundi may show no changes in the early stages. Later, however, temporal pallor of the disc develops which may persist even when vision has been restored to normal.

Treatment. Due to war conditions, it was not possible to carry out a standard treatment. Some cases were treated with brewers yeast (6 dr. to 1 oz., daily) and a mixture of cod-liver oil (2 dr. with 15 drops tincture of ferri perchlor). One third of this dose was taken three times a day. The yeast had been kept in sealed tins for two years, but was apparently efficacious in most cases. When this supply was exhausted, a small stock of food yeast made by Colonial Yeast, Ltd. was made available. This did not seem to be as effective as brewers yeast. Finally, trade preparations of the vitamin-B complex (Be Forte) were purchased. Parents were encouraged to add one-half pint of milk, one egg, and vegetables to the daily diet. A few cases received thiamine (5 gr.,

three times a day) or riboflavin alone, but no satisfactory conclusion could be drawn from these.

Results. Fifty patients made satisfactory progress (19 boys, 31 girls). Of these, 26 recovered 6/9 to 6/6 vision; 19 were improved with vision from 6/12 to 6/24. In one case, vision in the right eye was improved to 6/6, while that in the left eye remained at 6/36. Of the remaining 24 patients, three attended the eye clinic only twice. One patient who had visited the clinic five years previously had vision of 6/60 and optic atrophy. The other patients came under treatment late in the course of the disease or attended the clinic irregularly.

Prognosis. How much of the success of the treatment was due to the general increase in diet cannot be estimated. Milk and eggs were ordered for daily use, but it is almost certain that 75 per cent of the children received very little or none at all of these foods. Those cases in which the general diet could be improved were cured rapidly, provided an early diagnosis had been made; that is, while vision was 6/12 or better. The time taken for restoration of normal vision varies from two months to a year or more depending, it would seem, largely on the general improvement

of the diet and, of course, on the severity of the lesion.

The associated deafness was improved in 5 out of 10 cases. The worst cases made no progress in either sight or hearing, even though their general condition became normal. It was noticed that improvement first began in the general condition, particularly in the mouth lesions. The over-red lips and glossitis were always a sign that eye symptoms still persisted. Many patients had healed oral lesions, although vision remained poor.

Cheilitis and glossitis are common among the poorer classes at all times. Under war and hurricane conditions, they are present even among the better economic classes, particularly from January to April each year. The association of cheilitis and glossitis with retrobulbar neuritis was noted by the writer eight years ago. The lips are an indication of the progress of healing. No case with impaired vision has been cured without the oral lesions being healed. In long standing cases, vision sometimes does not improve although the oral lesions are cured rather easily. The general health will usually return. Sight and hearing will not return, however, unless the patient is promptly treated.

NUTRITIONAL RETROBULBAR NEURITIS*

FRANK D. CARROLL, M.D.

New York

A distinct type of retrobulbar neuritis in children has been observed in Jamaica, British West Indies, for many years. A few months ago while in Jamaica I had the opportunity, through the courtesy of Dr. Dahlia Whitbourne of Kingston, to examine numerous children with this condition. Since that time I have had one patient with this disease in New York.

In 1936, L. M. Clark of Jamaica reported¹ on this condition. He found that this type of retrobulbar neuritis occurred most commonly between the ages of 8 to 14 years in malnourished children who frequently had rhagades of the lips. He stated that usually the parents or teachers noticed that the child was not seeing well; on examination it was impossible to improve the vision with glasses. Syphilis and foci of infection could be excluded as etiologic factors. Early in the disease, the optic discs appeared normal but later temporal pallor often developed. Since peripheral neuritis due to malnutrition in adults was well-recognized, and since these children showed other evidence of faulty diet, Clark treated his cases with cod-liver oil plus a good diet containing milk, eggs, and vegetables. These foods are excellent sources of natural vitamin-B complex. The average length of treatment for patients with 20/200 vision was 4½ months. Recurrences occurred in some patients who discontinued their treatment. Patients over 16 years of age were not common, and they did not respond well to treatment—possibly, he states, because atrophic changes had already taken place.

Dr. Whitbourne of Kingston, Jamaica,

has seen 1,069 patients with this condition in the past 12 years.² In 1945, she treated 74 such children. Through her coöperation many of these young patients came to the Kingston Eye Clinic for examination by Dr. Raynold N. Berke and me in February, 1946. Most of them had improved to a considerable extent on her treatment. Some of these had normal vision and no evidence of malnutrition. Examination of the more recent cases presented the following findings.

EXAMINATION OF CASES

Visual Acuity varied from 20/40 to 20/200. It was usually 20/70 to 20/200 when the patient was first seen in the eye clinic. The discs were normal in appearance early in the disease but later often showed marked temporal pallor. Pallor was sometimes seen in children who had made a complete recovery; that is, those whose vision had returned to 20/20 and who had no visual field defects.

Visual Fields which were satisfactory were difficult to obtain in many of the children because of their age. However, in 6 out of 12 older children tested, I was able to obtain definite central or centro-caecal scotomas. These scotomas were usually small. They were usually about 5° in diameter for a 1 mm. white test object at one meter. It was easier to demonstrate the scotoma with a 3 or 5 mm. red test object at one meter than with the smallest white objects. The peripheral field was normal.

Hearing. Approximately 10 percent of the children with retrobulbar neuritis had partial eighth-nerve deafness.

Other Evidence of Dietary Deficiency. Dr. Whitbourne³ states that all the children in her group showed skin or mucous-

* From the Department of Ophthalmology, College of Physicians and Surgeons, Columbia University, and the Institute of Ophthalmology, Presbyterian Hospital.

membrane changes considered characteristic of vitamin-B-complex deficiency. These consisted of excoriations at the angles of the mouth and occasionally at the outer canthi, greasy desquamations along the nasolabial folds, sore mouths, and sore tongues. One or all of these signs might be present. No gross neurologic signs were noticed except those of the second and eighth nerves.

Prognosis. Of 72 patients treated 42, or 58 percent, were cured or markedly

prove the diet of the child. The English government has started a campaign to grow a special yeast in Jamaica. This is expected to decrease the number of patients showing evidence of vitamin-B-complex deficiency.

A CASE REPORT

G. O., a man aged 24 years, was seen in New York in March, 1946. He had lived in Jamaica all of his life. At the age of 11 years, blurred vision and decreased

Fig. 1 (Carroll). Visual fields in the case of G. O. show dense centrocaecal scotomas and normal peripheral fields.

improved. The remainder improved slightly or not at all. If a good diet is not continued, the condition may recur. Clark reported one patient who had three attacks over a period of five years. The first time vision improved under treatment from 20/200 to 20/20. Thirty months later, vision improved from 20/200 to 20/40. Two and one-half years later, vision was 20/120 and failed to improve.

Treatment. At the present time, brewers yeast is the treatment of choice in Kingston. Every effort is made to im-

prove the diet of the child. The English government has started a campaign to grow a special yeast in Jamaica. This is expected to decrease the number of patients showing evidence of vitamin-B-complex deficiency.

hearing were noticed. He was seen by the leading ophthalmologists in Kingston, but no improvement had resulted. He recalled taking cod-liver oil but stated that his condition had remained stationary for the past 13 years. Examination showed vision to be 20/200 in both eyes, unimproved. Fundus examination showed marked temporal pallor in both eyes; otherwise, the fundi appeared normal. Visual fields (fig. 1) showed dense centrocaecal scotomas and normal peripheral fields. Kline and Wassermann blood tests were negative. Skin

and mucous membranes were not unusual, and the patient now seemed well nourished. There was no family history of eye disease. Hearing tests were performed by Dr. Edmund P. Fowler, Jr., who reported "a peculiar type of nerve deafness with the greatest loss (by the audiogram test) at a frequency of 1,000" (fig. 2).

COMMENT

The retrobulbar neuritis found in the children of Jamacia resembles very close-

dry beriberi with shooting pains in their feet and legs; still others had wet beriberi with marked edema. It was usually at this time that decreased vision was noticed—a condition which usually came on gradually. If the prisoner's diet was improved, the vision often improved, but most of the men were on a cruelly inadequate diet for several years. The visual acuity of the patients I examined ranged from 20/70 to 20/200; the discs showed definite pallor temporally in some; in

Fig. 2 (Carroll). Chart of the audiogram test in the case of G. O.

ly that seen among American soldiers released from Japanese prisoner-of-war camps. Through the courtesy of the Eye Department at the Valley Forge Hospital, I had the opportunity, in December, 1945, of examining some of these young men. Most of them had been taken prisoner by the Japanese at Bataan or Corregidor in the Spring of 1942. They were given very little food of any kind and within 2 to 3 months most of them developed multiple deficiency diseases. Some described typical skin and mucous-membrane lesions of pellagra; others had

others, the pallor was slight. Peripheral fields were normal. A small pericentral or centrocaecal scotoma was always present. The densest part of the scotoma seemed to be at the center rather than between the blind spot and the point of fixation as in tobacco-alcohol amblyopia.

A typical history is that of an American soldier captured in May, 1942. He was starved from the time of capture. In two months his vision began to decrease; in four months his vision was very poor, and he had dry beriberi, dermatitis, and stomatitis. His diet was then improved

slightly which brought a slight improvement in his vision. He said that for the past year he had noticed no change in his vision. Vision was 20/70, O.U. Visual fields were as illustrated (fig. 3), and the discs showed slight pallor temporally.

T. N., a clergyman, was seen by me in May, 1946, through the courtesy of Dr. James Regan of Boston. The patient's story emphasizes how a deficiency disease

scotomas could be plotted. This patient said that, out of 110 prisoners in his group, 12 had had similar symptoms.

Ridley in a very instructive article⁴ describes small, sharply demarcated central scotomas in 90 released prisoners of war. He states: "Quite a high proportion of the amblyopic have become nerve deaf though other neurological disorders have so far seldom been found." This, of

Fig. 3 (Carroll). Visual fields of an American soldier captured by the Japanese in May, 1942.

may be precipitated by intercurrent infections.⁴ During the first two years of imprisonment, after his capture in Burma by the Japanese, the clergyman's general health and vision remained fairly good. However, his diet was poor and his weight decreased from 190 to 175 pounds. In December, 1944, he developed amebic dysentery and in the next three months his weight decreased from 175 to 90 pounds. His vision decreased markedly during this period. His legs became swollen and numb. Beriberi was present. His general condition has improved markedly since his liberation in 1945, but his vision (O.U., 20/200, unimproved), he feels, has not improved. Both discs show marked temporal pallor, and small central

course, is similar to the finding in Jamaica. Ridley attributes the lesion to general malnutrition rather than to simple deficiency of the vitamin-B groups. Reports of other workers⁸ are similar.

Kronfeld⁵ described a type of retrobulbar neuritis in China. This occurred in young adults on very poor diets and was characterized by small central scotomas of about 2 to 3 degrees in diameter. Many cases of nutritional retrobulbar neuritis have been reported from West Africa⁶ and the Orient.⁷

In considering the etiology of this Jamaican retrobulbar neuritis, we have to decide whether or not it is nutritional in origin and, if so, what essential food elements are lacking. Serologic tests exclude

syphilis as a cause. The possibility that this condition is hereditary has been taken into account, but no family history of similar eye disease is obtainable. Recovery seems to depend on improvement in the patient's diet, or at least adding yeast to the diet he was receiving while the optic-nerve disease was developing. Yeast contains all the vitamin-B fractions, and it is possible that the fraction which is responsible for curing the skin and mucous-membrane lesions may be different from that which favors recovery of the optic nerve.

SUMMARY

Nutritional retrobulbar neuritis has been studied in children in Jamaica. The condition appears to be similar to the syndrome found in numerous released prisoners of war. Although it seems certain that the disease is nutritional in origin, these patients were on diets deficient in many essentials. It is, therefore, impossible in the light of our present knowledge to be sure which factors produced the loss of vision.

A CASE OF A SPLINTER OF GLASS IN THE ANTERIOR CHAMBER OF FOUR YEARS' DURATION

WILLIAM BROWN DOHERTY, M.D.
New York

Probably the most difficult intraocular foreign body to remove from the eye is glass. This difficulty is due, first, to the fact that most glass does not show up in X-ray studies and cannot be localized. Secondly, the operator in the majority of cases is dealing with a very small splinter of glass which, in order to remove, must require operating with a high-powered loupe and very brilliant illumination. In the third place, particles of glass are always jagged, are hard to grasp, and their irregular contour causes them to adhere to the surrounding structures. In attempting to remove them a pair of duck-billed forceps is the best instrument to use. Fourthly, glass is nonmagnetic, and its removal from the anterior chamber depends upon two methods: (1) opening the anterior chamber and mechanically picking the foreign body from it; (2) making an incision into the anterior chamber with the patient facing and looking downward which causes the ensuing gush of aqueous to expel the material.

REPORTS IN THE LITERATURE

In looking over the literature, I found a number of cases which were very interesting. During a meeting of the Royal Society of Medicine, Section of Ophthalmology,¹ Mr. Victor Purvis presented a woman, aged 54 years, with a piece of glass in the anterior chamber. An attempt was made to remove it, but there was a certain amount of wedging between the lens and the cornea. He then tried to do an iridectomy but the glass prevented him from getting an effective hold of the iris. With the slitlamp, a movement of soft lens matter was visible under the capsule of the lens which led to the assumption

that the case was becoming morgagnian. Mr. Purvis stated that he could not remember having seen such mobility before.

During the same meeting,¹ Mr. Frank Juler referred to a case in which he had removed a splinter of glass which was free in the anterior chamber. He had made an incision as for Saemisch's section, with the patient facing and looking downward; the ensuing aqueous drip carried the splinter into the section, where it was easily picked out after the patient had resumed the usual position on his back. In a similar case, he made a puncture with a broad needle in the usual position. The patient was then turned over so that he looked downward; a touch on the cornea released the aqueous, and the foreign body was recovered from the lower fornix.

Dr. John Marshall suggested that, in cases of nonmagnetic foreign bodies in the anterior chamber, a section downward, such as Dr. Traquair employed in his intracapsular extractions, gave a good approach to the angle of the anterior chamber. A stitch was placed in the conjunctival flap and the cornea turned upward so that the major portion of the iris was exposed, and the foreign body was easily removed by blunt forceps.

Azarova² reported two cases of glass in the eye which occurred during air raids. The glass remained in the eye for long periods. He states that glass is difficult to locate with the X ray; that it can remain in the eye for a long time without producing inflammatory phenomena; that, if left alone, it appears to be well tolerated by the eye; that the eyeball tends to extrude the foreign body, often spontaneously, after remaining in

the eyeball for a long time. He reports two cases. In the first, a particle of glass lodged in the pars planum of the ciliary body in the left eye of a civilian during an air raid. The patient developed an iridocyclitis. He was under treatment for 10 weeks during which time an unsuccessful attempt was made to remove the foreign body. After recurring attacks of irritation complicated by papillitis, the eye became quiet and remained so for the year it was under observation. There was a retinal detachment and particles of glass could be seen in the vitreous. The second case was also of an injury sustained during an air raid. The patient was found to have a retinal detachment and the X ray revealed a small intraocular foreign body with a large piece of glass in the antrum. The eye, although blind, remained quiet for 15 months, at the end of which time a particle of glass was spontaneously extruded from the original wound. Within the next three days the eyeball was lost from panophthalmitis, in spite of the vigorous use of sulfonamides.

CASE REPORT

P. McG., aged 17 years, was, on August 19, 1942, experimenting in a laboratory in the home of a friend when an explosion took place while they were working on glass and steel. The explosion was quite severe, blowing off the arm of one of the experimentors and seriously wounding three or four others. They had obtained a mixture of potassium nitrate, red phosphorus, sulphur, and charcoal, and these ingredients were placed in a mayonnaise jar. After it had been stirred three or four times, the mixture exploded. The injured were removed to a hospital, and it was found necessary to enucleate the right eye of my patient. This patient states that the left eye did not annoy him at the time of the enucleation, but about 1½ years after the removal of the right eye,

he noticed a diminution of vision in the left eye which gradually became worse, with very slight pain. He experienced marked photophobia and lacrimation. An X-ray picture was taken at the time of the accident, but no intraocular foreign body was found. The X-ray picture of his teeth was negative, and a complete laboratory examination was also negative.

We first saw this patient on August 8, 1945, at which time the eye presented the following condition. Vision in the left eye was 20/40 and could not be improved. The cornea presented a large vascularized infiltration which covered its lower half and was a textbook picture of a bullous keratitis. The upper part of the cornea was slightly hazy, and the vitreous and fundus, which could not be clearly seen, appeared normal. Principal medication had been atropine, and dark glasses were worn when the eye presented symptoms of irritation. The patient also had been taking large quantities of vitamins. This treatment had been prescribed for a period of over four years. He had consulted a number of ophthalmologists but no evidences of intraocular foreign material could be definitely made out. He had no atropine conjunctivitis. I suggested the use of homatropine. Perhaps, shocking the iris in this way without causing so much dilatation of the pupil would help to alleviate the marked symptoms of irritation which the eye presented. He stated, however, that his eye felt better when using atropine. When not under the influence of atropine, the pupil reacted well to light and accommodation. There were no synechiae and no deposits on the anterior capsule of the lens. He was immediately referred to Dr. Irving Schwartz of the X-ray Department of the New York Eye and Ear Infirmary for a radiographic examination of the left eye for a possible intracular foreign body of glass or steel. The report is as follows:

"There are several small foreign bodies in the vicinity of the left orbit. The density of the shadows they cast corresponds to glass. There is no evidence (X ray) that any of these foreign bodies are in the globe."

An examination with the slitlamp two or three times a week was always negative for any foreign material. The examination was somewhat difficult due to the intense photophobia and the lacrimation which was always increased when the eye was subjected to strong light. A few drops of a 2-percent solution of holocaine instilled into the eye greatly facilitated the examination.

On December 12, 1945, while studying the whole anterior chamber, I was positive that I saw a piece of glass in the angle of the anterior chamber around the 4-o'clock position. It had the appearance of a yellowish prismatic crystal about $2\frac{1}{2}$ mm. wide and about 5 mm. long. The drawing (fig. 1) gives a good idea of how the foreign body appeared. Three days later, Dr. John Dunnington of the Institute of Ophthalmology of the Presbyterian Hospital confirmed my diagnosis, and I decided to remove the glass. The case was also shown to Dr. Wendell L. Hughes at the New York Eye and Ear Infirmary. Dr. Pfeiffer of the Institute of Ophthalmology, of the Presbyterian Hospital very kindly made X-ray studies of the orbits of my patient with the following report:

"Films of the orbits in the Caldwell position reveal many fragments in the tissues of the face and lids of the right eye. One fragment measuring approximately 2×3 mm. of glass density can be seen in the left orbit and would appear to be in the eye. Bone-free films which include approximately 16 mm. of the anterior segment of the left eye show a number of particles in the lower lid and

none definitely within the eye itself."

A second X-ray study made by Dr. Pfeiffer is as follows:

"The faint shadow of glass density previously noted in the left orbit is localized outside of the eyeball with the contact lens."

OPERATIVE PROCEDURES

The glass could not be seen with the naked eye, but with a small hand slitlamp

Fig. 1 (Doherty). Bullous keratitis with glass near the angle of the anterior chamber between the 3- and 4-o'clock positions.

and a good Zeiss loupe there was definitely no question regarding the cause of this patient's discomfort over a period of years (four). He entered the New York Eye and Ear Infirmary, and I attempted to remove the foreign body. It appeared in close apposition with the posterior surface of the cornea, and my idea was to make an incision at the limbus with a keratome, posterior to the glass at its lower border or spear-shaped edge, the point of the keratome coming to the edge of the lower part of the glass. It was then my intention to enlarge the incision upward with a pair of Stevens' scissors long enough to grasp the foreign body and extract it with a pair of duck-billed forceps.

My source of illumination was the ordinary eye-operating lamp, such as is used for any intraocular operation, and

to get better concentration of the light, I used a hand condensing lens. This mode of illumination proved very faulty, as it was impossible to get a good view of the glass in the anterior chamber. My troubles

Fig. 2 (Doherty). Black-stained cataract knife and keratome which do not cast dazzling reflections.

were augmented by irregular reflections from the keratome and speculum. In this type of case, a hand slitlamp should be used. In making my incision the dazzling from the keratome obliterated the foreign body no matter from what angle I viewed it. In endeavoring to change the position of the keratome very slightly, the anterior chamber was lost with a gush of aqueous but no prolapse of the iris. I examined the site of the foreign body for some time but could not see it. Finally, I introduced a long olive-shaped spoon into the anterior chamber and attempted to scoop out the foreign body, although I was unable to see any evidences of it. Atropine was instilled into the eye and a dressing was applied. Healing was uneventful.

I continued to examine the eye two or three times a week with a slitlamp but could not find any evidences of the foreign body. In April, 1946, because of the bullous keratitis, I advised the patient to stay indoors; to use penicillin ointment with a patch three times a day for one hour at a time. From then on, there has been a gradual improvement until at this writing, July 27, 1946, the eye is quiet. There is no circumcorneal injection, no photophobia, and only slight lacrimation

when examined with strong light. Bullous keratitis has completely disappeared, and the opacity is a faint macula over the lower border of the cornea which is still clearing. The pupillary area is clear. Vision under homatropine is: 20/15 with a +0.50D. sph. \ominus +0.50D. cyl. ax. 75°. The pupil reacts well to light and accommodation. There are no opacities on the anterior capsule of the lens, and the media and fundus are normal. Small pieces of glass are being extruded spontaneously from the upper and lower lids of both eyes at the present time.

CONCLUSIONS

This case was very interesting and instructive.

1. I am positive that in similar cases the hand slitlamp is the best source of illumination.

2. The eye speculum and keratome should have a dull or black finish to prevent dazzling. I presented my ideas to Victor Mueller of Chicago, and Mr. George M. Wallerich, president of the company, had two cataract knives and two keratomes made with a black nickel or acid finish (fig. 2). I have used these instruments, and it is my opinion that they will supplant the highly polished instruments that are now in vogue. I have asked many of my colleagues and they say that the idea is excellent. Dazzling and reflections from highly polished instruments have annoyed them too. If one does not wish a black finish, a dull-satin finish is preferable to the highly polished one. For the ophthalmologist, the black-finished speculum and black-finished cataract knife and keratome can be used with more precision because they are nonreflecting and because of their contrast with the cornea.

I wish to thank Drs. Dunnington, Pfeiffer, Hughes, and Schwartz for their interest in this case, and also to thank

Miss Mary R. Brown and Miss Margaret Markham of the photographic department of the New York Eye and Ear Infirmary for their painstaking efforts in obtaining a photograph of the glass after many exposures taken at different angles. I wish

also to express my appreciation to the men of the Peter Junco photographic studio, New York, for their excellent photograph of the dark-stained instruments.

150 West 55th Street (19).

PERSONALITY PATTERNS OF WHITE ADULTS WITH PRIMARY GLAUCOMA*

HELEN L. HIBBELER, M.S.W.
St. Louis, Missouri

In recent years there has been an increasing emphasis on the study of psychosomatic medicine. Physicians, psychiatrists, and social workers have explored the emotional components of various illnesses, and in some of the diagnostic groups personality patterns have emerged.¹ Very little research has been done in the psychic factors of ophthalmic disorders. No previous studies have been made, to my knowledge, to determine if there is a personality pattern common to these patients. However, rather conclusive evidence has been found to support the thesis that emotional factors play a prominent role in the treatment of many patients suffering from glaucoma.

A selected group of 27 glaucoma patients was examined to ascertain: first, whether patients with primary glaucoma exhibit greater personality disturbance as

measured by a personality inventory than would the normative group for that inventory; and second, whether a demonstrable variation of personality patterns could be shown to exist when the patients were classified according to various social and medical data. The ultimate purpose in obtaining this information was to enable ophthalmologists and social workers to give glaucoma patients more effective treatment.

Because of the seriousness of the disease, if untreated, and the emotional factors involved, an agreement was made several years ago between the ophthalmic and the social-service staffs of Washington University clinics that all patients with the diagnosis of glaucoma would be referred to a social worker for social investigation and social therapy. Names of these patients and various identifying information are kept in a case-holding file from the time the diagnosis of glaucoma is made. The active file on October 1, 1945, listed 154 patients. The 27 patients

* Summarized from a dissertation presented to the George Warren Brown School of Social Work of Washington University in partial fulfillment of the requirements for the degree of Master of Social Work, June, 1946.

participating in this study were drawn from this number.

Several qualifications governed the choice of this group. Only those patients diagnosed as having primary glaucoma were studied. Since the personality inventory selected was standardized for white patients, a second limitation was made by including only white persons. A third limitation permitted the inclusion only of those patients who were currently attending the glaucoma clinic of Washington University Eye Clinic.

Of the 154 patients in the active file on October 1, 1945, 60 were Negro and 94 were white. Of the white group, 20 were diagnosed as congenital or secondary glaucoma, and 74 as primary glaucoma. Examination of these 74 patients was planned, but 47 had to be excluded for reasons ranging from geographical inaccessibility to diagnosed mental illness.

THE MINNESOTA MULTIPHASIC PERSONALITY INVENTORY

The Minnesota Multiphasic Personality Inventory² was the instrument selected through the assistance of Dr. C. F. Jacobsen, medical psychologist and assistant dean of the Washington University Medical School.* Published originally in 1942, the inventory was devised by Dr. S. R. Hathaway, associate professor of psychology, and Dr. J. C. McKinley, professor of neuropsychiatry at the University of Minnesota, to indicate marked deviations from normal personality trends. The booklet form was used, containing 566 questions arranged in such a way that all the answers could be recorded on a single International Business Machines scoring sheet. The first 366 items were used, because scoring keys and norm tables have been developed only for this number. The subject is asked to reply

"true," "false," or to make no reply if it is something which he does not know about or which does not apply to him.

It consists of three validating scales and nine scales to measure personality trends. Of the validating scales, the Question Score (?) indicates the number of unanswered items; the Lie Score (L) measures the degree to which the subject may be attempting to falsify his scores by always choosing the response that places him in the most acceptable light socially; and the Validity Score (F) indicates the rationality and pertinency of the subject's responses.

The Hypochondriasis Scale (Hs) is a measure of the amount of abnormal concern about bodily functions. It is characteristic of the hypochondriac that he is immature in his approach to adult problems, tending to fail to respond with adequate insight.

The Depression Scale (D) measures the depth of the clinically recognized symptom or symptom complex, depression. The depression may be the chief disability of the subject or it may accompany, or be a result of, other personality problems. A high D score indicates poor morale of the emotional type with a feeling of uselessness and inability to assume a normal optimism with regard to the future. It further suggests a characteristic personality background in that the person who reacts to stress with depression is characterized by lack of self-confidence, tendency to worry, narrowness of interests, and introversion.

The Hysteria Scale (Hy) measures the degree to which the subject is like patients who have developed conversion-type hysteria symptoms. Definite symptoms may never appear in a person with a high score, but under stress he is likely to become overtly hysterical and attempt to solve the problems confronting him by the development of symptoms.

* Dr. Jacobsen is now dean of the Graduate School, University of Iowa.

These cases are more immature psychologically than those in any other group. The subject with a high Hy score may have a real physical pathologic condition, either as a primary result of concurrent disease, such a diabetes or cancer, or as a secondary result of the long time presence of the psychologic symptoms.

The Psychopathic Deviate Scale (Pd) measures the similarity of the subject to a group of persons whose main difficulty lies in their absence of deep emotional response, their inability to profit from experience, and their disregard of social mores.

The Interest Scale (Mf) measures the tendency toward masculinity or femininity of interest pattern; a high score indicates a deviation of the basic interest pattern in the direction of the opposite sex.

The Paranoia Scale (Pa) was derived by contrasting normal persons with a group of clinic patients who were characterized by suspiciousness, oversensitivity, and delusions of persecution, with or without expansive egotism.

The Psychasthenia Scale (Pt) measured the similarity of the subject to the psychiatric patients who are troubled by phobias or compulsive behavior. Frequently a psychasthenic tendency may be manifested merely in a mild depression, excessive worry, lack of confidence, or inability to concentrate.

The Schizophrenia Scale (Sc) measures the similarity of the subject's responses to those patients who are characterized by bizarre and unusual thoughts or behavior. There is a splitting of the subjective life of the schizophrenic person from reality so that the observer cannot follow rationally the shifts in mood or behavior.

The Hypomania Scale (Ma) measures the personality factor characteristic of persons with marked overproductivity in

thought and action. The hypomanic patient has usually gotten into trouble because of undertaking too many things. His activities may interfere with other people through his attempts to reform social practice, his enthusiastic stirring up of projects in which he then may lose interest, or his disregard of social conventions.

It was necessary to read the items to all but six of the patients studied. The results indicated that this variation from the proscribed procedure for administering the inventory did not affect the validity.

The standard-score equivalents of the raw scores were obtained from prepared tables and placed on profile charts for each patient. The patients were then classified according to various social and medical data, and their scores analyzed for similarities or differences.

ANALYSIS OF DATA

The most important finding of the study was that more than two thirds of the patients showed marked deviations on one or more of the personality scales. This concentration of extreme deviating scores is distinctly unusual and stands in sharp contrast to Hathaway's finding that but 5 percent of the original normative group showed such marked deviations, illustrated in Tables 1 and 2. All scores below 60 were considered to be within normal ranges. Scores between 60 and 69 indicated a definite personality trend, while scores 70 and above suggested severe personality disorders.

It is clearly evident that the group of patients with primary glaucoma show severe personality deviation, in many instances with scores suggesting behavior bordering on the psychotic. It is of further interest that four female patients were omitted from the study, one because

she had been admitted to a mental hospital, and three because their personality disturbances and great feeling of persecution, as evidenced by their overt behavior in the clinic and conversations with the

No personality pattern was found to be common to the group as a whole. However the "average" profile for the male group of 15 patients was distinctly different from the "average" profile of the

doctors and social workers, were sufficiently severe to render questionable the value, either to them or to the study, of their inclusion. The "average profile," as determined from the mean scores of all the patients on the nine scales is illustrated in Chart 1.

12 female patients, illustrated in Chart 2.

It may be observed that the men had higher scores on the scales Depression and Hysteria; the women had higher scores on the scales Paranoia and Schizophrenia. The statistical probabilities computed for these groupings provide

good basis for further study among glaucoma patients. The personality trends indicated by the inventory were substantiated by all the social information available.

The most significant findings when the patients were classified according to various medical data were on the basis of intraocular pressure. Previous writers have found that increase in intraocular pressure is frequently precipitated by anxiety states.³ The medical records of these 27 patients were studied and divided into the two groups "tension consistently low"

Chart 1 (Hibbeler). Profile chart showing the "average" profile of the glaucoma patients as determined from the mean scores on the 12 scales.

and "other." The first group included all those whose tension, after the first two months of treatment at Washington University Clinics, was never recorded as higher than 25 mm. Hg (Schiotz). "Other" included all those whose tension was higher than 25 mm. one or more times, or remained consistently higher. There was a very noticeable difference between these two groups, as may be seen in Chart 3. Those patients whose tension remained low have higher scores on almost every scale, the most marked difference being in paranoia, where the average score for the "low" group is 14 points higher than for "other." Dr. Hathaway believes this profile is not surprising, for two reasons. First, the more rigid and successful a hysterical symptom, the less evidence has been found for psychologic stress. The successful conversion symp-

tom seems to "drain off" the psychologic stress. The second point of interest is that the dominant pattern tends toward the hysterical-type curve. This, together with depression, is the accepted picture of psychologic stress generally.

Chart 2 (Hibbeler). Profile chart showing the "average" profiles of glaucoma patients grouped according to sex, as determined from the mean scores of each group on the 12 scales.

Chart 3 (Hibbeler). Profile chart showing the "average" profiles of glaucoma patients grouped according to response to medical care.

In an attempt to determine the importance of suggestion and identification with a loved person in the choice of site for physical handicap, each patient was asked how many of his relatives had visual disorders. Each one he mentioned in reply was noted, whether it were a refractive error or complete blindness, in the belief that if it were not important to

him, he would not have mentioned it. Approximately one third of the patients reported such relatives, and this group exhibited scores on three scales much higher than those with no relatives with a visual handicap. These average scores were in the psychotic ranges on hypochondriasis

central vision, diagnosis of chronic-simple or acute-congestive glaucoma, or length of time since the diagnosis was made, except in some cases to support the trends for the population as a whole.

CONCLUSIONS

This preliminary survey of patients with primary glaucoma has shown that they exhibit more frequent disturbances of personality as measured by the Minnesota Multiphasic Personality Inventory than do unselected clinic patients. The trend of personality disturbance for the male patients is in the direction of "depression" and "hysteria;" the trend for the female patients is in the direction of "paranoia" and "schizophrenia." The group of patients whose intraocular pressure remains within normal limits with medical treatment have slightly greater probability for marked deviation of scores than the group whose tension is occasionally or always elevated. Statistical analysis provides adequate basis for further study of these trends, which may furnish knowledge valuable in planning medical and social therapy for patients with primary glaucoma.

5330 Pershing Avenue (12).

SIGNIFICANCE OF ACTION OF PAREDRIENE ON THE OCULAR TENSION OF RABBITS*

ERNST SCHMERL, M.D.[†]
Toledo, Ohio

In a former study¹ it was shown that instillation of 1-percent paredrine had no appreciable effect on the ocular tension in most rabbits. The tension was determined 30 minutes or four hours after administration of the drug. Some of the animals showed, however, a definite increase in pressure. This paper deals with those factors which were responsible for the variations obtained in the previous study.

METHODS AND MATERIALS

Nine rabbits were used in the experiment. Five rabbits were New Zealand white, three Flemish giant brown, and one Chinchilla. The ocular tension was determined tonometrically with 5.5 gr. and 10 gr. weights. The average values were obtained from two readings which were made with each set of weights at each recording. The readings were calculated for normals and also 10 to 15 minutes after application of paredrine. A change of 3 mm. Hg or more was regarded as a definite increase in pressure. The paredrine was applied with an applicator to the entire corneal margin. Because of the local application, the action of the paredrine was restricted for a short period to the pericorneal blood vessels. In control experiments 0.5-percent salt solution, 0.1-percent pilocarpine, and 0.05-percent atropine were used. After the tonometric studies were completed, the animals were examined under nembutal

narcosis with a corneal microscope and a slitlamp.

RESULTS

Two of the white rabbits persistently showed an increase in tension with paredrine. Three other white rabbits had an

Fig. 1 (Schmerl). Drawings of eyes of two rabbits. a, Chinchilla rabbit with a relatively poor pericorneal vascular bed. b, pericorneal region in a white rabbit with a rich vascular supply. Due to the difference of the degree of vascularity of the pericorneal beds, there was a corresponding quantitative vasoconstriction response. The number of the pericorneal vessels which were constricted resulted in variable intraocular pressures due to varying degrees of interference with drainage of the aqueous.

[†] Research ophthalmologist of the Snyder Ophthalmic Foundation.

increased tension in most of the determinations. The colored rabbits showed an increase in 40 percent of the measurements. Examinations with a corneal microscope revealed an extensive peri-

corneal vessel bed in the two rabbits with persistently high tension. The remaining three white rabbits showed a definitely smaller vascular bed. The pericorneal vessels in the brown animals were smallest in number. Some of the vessels of one of the brown rabbits failed to contract after repeated applications of paredrine. In the three white rabbits, the extensive pericorneal vascular bed was associated with

aqueous is assumed to depend on the semipermeable activity of the capillary walls and the difference of osmotic pressure. The ciliary body is accepted in this and other concepts as the significant origin of the humor. In the secretion theory, it is assumed that the aqueous is secreted by the epithelium of the ciliary body.

The outflow of the aqueous humor is believed to be controlled by two mecha-

presence of aqueous veins described by Ascher.²⁻⁴ A rhythmic inflow of a clear watery fluid into veins carrying blood was observed in these animals with a corneal microscope of 29× magnification.

DISCUSSION

There are three concepts regarding the inflow of aqueous humor into the anterior chamber of the eye. In the filtration concept, the ciliary body vessels are accepted as the principal supply of aqueous by virtue of the inequality between the hydrostatic pressure of these vessels and that of the posterior chamber. In the dialysis concept, the circulation of the

nisms, hydrostatic and osmotic forces, with the iris and Schlemm's canal being the principal foci of reabsorption of the humor.

There are considerable data to indicate that the circulation of the aqueous is continuous and proceeds at a rate of 1 to 4 cu. mm. per minute.⁵⁻⁸ Asher supplied morphologic proof of presence of circulation of the aqueous by his discovery of the aqueous veins.²

Intraocular pressure normally approximates 18 to 28 mm. Hg. The pressure depends on the inflow, outflow, and the continuous circulation of the humor. Interference with the outflow of the aqueous or of its circulation, or an increase in the

inflow will result in the elevation of the pressure.

Various drugs have been employed in an effort to clarify the concepts of inflow, outflow, and of the continuous circulation of the aqueous. The action of a drug on the vascular system is either one of vasoconstriction or dilatation. It is maintained that vasoconstriction outside of the eye produces an increase in the ocular tension due to a concomitant vasodilatation of the vessels within the eyeball.⁹ The pericorneal and episcleral vessels must be considered as outside the eyeball. Contraction of the intraocular vessels results in a drop of intraocular pressure. In the instance of adrenalin, it was found that the route of administration may produce varying actions. When injected intravenously or into the subconjunctiva, there is a decrease, sometimes preceded by a slight increase,¹⁰ in the intraocular pressure.¹¹⁻¹⁴

In these experiments, paredrine was used. Its action is similar to that of adrenalin. Application of the drug to the pericorneal vessels along the entire margin produced a constriction of these vessels followed by an increase in the intraocular pressure. The relative vascularity of the pericorneal region apparently determined the frequency with which the animals responded to application of the

drug by an increase in ocular tension.

These experiments suggest that there is a continuous circulation and that the outflow of the aqueous occurs in part through Schlemm's canal into the pericorneal vessels. It may also be inferred from these experiments that the circulation of the aqueous is controlled by hydrostatic pressure as one of the forces.

SUMMARY AND CONCLUSION

Paredrine was applied locally to the pericorneal vessels of the eye. There was a resultant increase in the intraocular pressure which was dependent on the extensiveness of the vascular bed in the pericorneal region. Paredrine produced a local vasoconstriction. The rise of intraocular pressure paralleled the quantity of the pericorneal vessels which were constricted by the local application of paredrine. The vasoconstriction interfered with drainage of the aqueous. These experiments suggest the presence of a continuous circulation of the aqueous and the influence of hydrostatic pressure as one of the forces in circulation of the humor. There is also an indication of the importance of Schlemm's canal as one of the outlets of the aqueous.

SOME METHODS OF LID REPAIR AND RECONSTRUCTION*

III. SOCKET RECONSTRUCTION WITH EPIDERMIS

SIDNEY A. FOX, M.D.

New York

The ideal lining for a socket is mucous membrane. Where a slight deficiency exists, readjustment of tissues by means of a V-Y or Z plasty may be all that is necessary. Occasionally, small conjunctival grafts from the normal fellow eye may suffice. If larger grafts are needed, buccal mucous membrane (labial, or malar, or both) may be used. However, when more than half the socket has been obliterated, one must resort either to multiple mucous-membrane grafts or to an epidermic graft. I prefer the latter and, this report is limited to a discussion of the use of epidermis in eyeless sockets which require large grafts.

In 1921, Wheeler¹ presented an excellent method for total or subtotal reconstruction of an obliterated socket with epidermis. Briefly, the technique consists of dissecting the lids away from the orbital contents. The dissection is carried down below the lower orbital rim to the periosteum, behind the canthi, laterally, and behind the orbital rim above. A form, or stent, of dental compound is molded

to fit the socket. An epidermic graft is then taken, preferably from the upper outer aspect of the thigh, wrapped around the stent, epithelial side inward, placed in the socket, and a firm pressure dressing is applied. This method is as good today as it was 25 years ago.

After using this method for some time, I noticed that the stents tended to be the same shape and in most cases, approximately the same size; that is, about 40 by 30 by 4 mm. It seemed obvious, then, that if an acrylic form of the proper size and shape were available, it would do away with the awkward, time-consuming, dental-molding-compound technique. Accordingly, a series of these acrylic forms in graduated sizes was made up by our plastic eye laboratory (fig. 1). The plastic material is a polymer of methyl methacrylate which is used in the manufacture of plastic eyes. The largest form measured 42 by 32 mm., the smallest 38 by 22 mm. They were 3.5 to 4.0 mm. in thickness. For practical purposes, only the three largest sizes were actually used, and the one most frequently employed measured 38 by 28 mm., which is slightly smaller than that suggested by Wheeler. Experi-

* From the Eye Center, Newton D. Baker General Hospital, Martinsburg, West Virginia.

ence has proved the value of these forms. They are sterilized by immersion in 70-percent alcohol for 20 minutes.

TECHNIQUE

After suitable infiltration of the operative site with a 1-percent solution of novocaine with epinephrine, the lids are dissected up from the socket contents. As advised by Wheeler, only the skin and orbicularis should be included in the dissection. If the tarsus is identifiable, it may

granulation tissue has been resected, the shrinkage is minimal and need not be feared. An acrylic form that will fit snugly into the socket and fill out its dimensions is then chosen. The form should not have to be forced in if a sufficient assortment of forms is available. This step should take only a few seconds. The socket is now ready for the graft.

Following the method of Padgett,² a piece of epidermis approximately 3 by 4 in. in size and 0.010 in. to 0.012 in.

Fig. 1 (Fox). Acrylic forms. Largest measures 42 by 32 mm., smallest measures 38 by 22 mm.

Fig. 2. Types of skeleton conformer used after removal of acrylic form.

also be included; if not, there is no great loss. Every attempt should be made to preserve as much of the lid edges as possible, for these will contribute greatly to the final cosmetic result. Unfortunately, in cases of severe trauma, this is not always possible. The dissection is carried downward beyond the orbital rim to the periosteum, laterally under the canthi, and above to the orbital roof. An external canthotomy frequently facilitates exposure and mobility of the lids, as has been pointed out by Wheeler.

The next step is to resect all fibrous and granulation tissue. This cannot be emphasized too strongly. Sad experience has shown that it is failure to remove all traces of such tissue that causes most of the subsequent shrinkage. The epidermal graft will shrink also, but, if it is placed on a bed from which all fibrous and

in thickness is cut from the inner middle aspect of the arm; the dermatome is placed on a previously prepared flat surface, such as a small table, with the epidermic graft still adherent to it. Two corners of the narrower dimension of the graft are grasped in small clamps, and enough of the graft is peeled away from the drum to permit the previously chosen acrylic form to be slipped under it. Then, as the rest of the graft is peeled off, it is wound around the entire form, epithelial side inward. A graft of this size allows for some overlapping and assures sufficient tissue so that stretching will not be necessary.

The dermatome cement causes the graft to adhere to the form and makes subsequent handling easy. Any one who has had experience with the dermatome knows that, unless powder is used, or

unless the graft is taken on a layer of oiled silk, cellophane, or some similar material, there will be trouble from the curling and gluing together of the graft. The method described here makes all this unnecessary, and the graft is ready for

need for this. Furthermore, damming up of secretions may prevent a "take."

The eye dressing is removed after seven days, excess graft between the lids removed, the surface irrigated with warm boric-acid solution, and the pressure

immediate insertion into the socket. This is done with the overlapped portion facing outward. The lids are not sutured together. A patch and several gauze fluffs, over which a firm pressure dressing is applied, complete the eye dressing. The donor site is covered with a strip of vaseline gauze and a snug bandage. When this is removed after 12 days, the site is usually found to be completely healed. No oiled silk nor similar material that prevents absorption of discharge should be used as part of the eye dressing. Since no skin sutures are used that may become adherent to the gauze, there is no

bandage reapplied for five more days. By this time, the graft has "taken" completely. The form may be removed, the socket irrigated, and all excess epidermic tissue cleaned away. The inside of the socket is coated with a thin layer of some bland sterile ointment, and a skeleton conformer (fig. 2) is inserted. An ordinary patch, which is changed daily, is applied, and the socket cleaned and irrigated. Since the conformer allows adequate drainage, it need not be removed. At the end of another week, a permanent prosthesis may be inserted.

The same procedure is used whether a

whole or partial socket is to be constructed, for the reason that, unless a piece of epidermis large enough to overlap is taken, it is hard to handle and one is not quite sure of its staying in place. Consequently, in all cases, total or sub-

technique is followed carefully, a "take" is practically assured.

DISCUSSION

Basically, the technique outlined does not differ much from Wheeler's method.

Fig. 5 (Fox). a. Obliteration of upper and lower fornices and outer half of socket following combat injury. b. Repair with epidermis. An external canthoplasty was performed later, to complete the repair.

total, enough epidermis is taken to cover the form completely. Since epidermis can easily be spared, and is quickly replaced, one need not hesitate to take a little too much. Too little may necessitate further surgery; too much prevents it. If this

The changes suggested here simply apply recent scientific advances and methods to Wheeler's technique to make it quicker, easier, and simpler to carry out. This was found necessary under war conditions where there was much work to be done,

and time was always at a premium.

The substitution of the acrylic form for the dental-compound stent does much to simplify the procedure. Molding of the dental compound mud-pie fashion is an irksome and wearisome business. The water in which the stent is fashioned must be the right temperature—about 120°F. If hotter than this, the stuff sticks to the

gather, the merits of the skin knife versus the dermatome for small epidermic grafts is a favorite controversial subject. After giving both instruments extensive trial, the dermatome is, for me, the ideal instrument for taking epidermic grafts, however small. The reasons are: (1) Facility in handling the dermatome is not much more difficult to acquire than dex-

Fig. 7 (Fox). a. All conjunctiva of socket obliterated by lye burn and socket contracted by fibrous tissue. Photograph was taken after enucleation. b. Repair with epidermic graft taken with skin knife. Note saving of caruncle, which is important cosmetically.

gloves like glue. If colder, it cannot be molded. It must be constantly dipped in hot then cold solution, first to soften then to harden, until the proper size, shape, and smoothness are obtained. Use of an acrylic form, on the other hand, does away with all this. Experience has shown that one of the three largest conformers pictured in Figure 1 is usually required. Correct size is easily and rapidly ascertained and, once decided on, the form is laid aside until the graft is taken. The whole operation can be done without hurrying in 30 to 40 minutes.

Use of the dermatome instead of the skin knife also adds to the smoothness of the procedure. Wherever plastic surgeons

terity in handling the skin knife. (2) A graft of uniform thinness is obtained at all times. (3) Simply by applying the dermatome cement to pattern, any size or shape of graft is easily obtained. (4) By using the technique herein described, curling, shrinking and adhesions of the graft are prevented. All these factors more than make up for the few minutes spent in setting up the dermatome and applying the cement.

Many donor sites offer themselves: the anterior abdominal wall, the back, the outer or inner thigh, and the arm. As the donor site, I prefer the middle of the inner aspect of the arm, for it is easily accessible, and the skin here is hairless, requiring only the usual routine, preopera-

tive preparation. Postoperatively, the site is easily dressed and causes the patient less inconvenience during convalescence

such a socket clean of debris, infection, and odor. Presumably, this is especially true of those sockets containing a mixed

than would the taking of a graft from the thigh or abdomen.

The matter of hygienic care of the socket after this type of operation is important. Much has been said and written concerning the difficulty of keeping

lining of epidermis and mucous membrane. After having placed a large number of socket grafts of various kinds, I must confess that I have noted little difference in either odor or discharge among the mucous-membrane, epidermic, or

mixed-graft socket. A large proportion of them become easily infected and have a muco-purulent discharge. To some extent, this is true of all empty sockets, grafted and non-grafted. It should be remembered that an empty socket does not have the benefit of a normal tear mechanism, which is the cleansing agent of the eye. When the lower punctum is absent, as it is in many cases of severe trauma, this is especially true. Tears, mucus, and debris tend to collect and stagnate. Low-grade infections are easily set up and are hard to clear. If epidermic grafts are too thick—and this is sometimes true of those taken with the knife—sebaceous material and epithelial debris will aggravate the condition. Use of the dermatome, which permits the taking of an exceedingly thin, uniform graft, tends to obviate this to a large extent.

The patient must be carefully instructed in the proper care of such a socket with careful cleansing and irrigations. This is a requisite in all these cases. When infection has set in, I have tried everything including the sulfonamides and penicillin in both ointment and liquid bases. In acute infections, penicillin ther-

apy is ideal. In the chronic conditions, however, I have, as yet, found nothing to replace 1- or 2-percent silver-nitrate solution firmly applied to the socket daily with an applicator. It works well on both mucous membrane and epidermis.

Six cases of epidermic socket grafts are pictured in Figures 2 to 8. Five of these figures present pictures of battle casualties; the sixth is of a private case in which the injury was caused by lye burn. These six cases have been chosen because each represents a somewhat different site of injury and type of problem. In only two cases was the skin knife used (figs. 6 and 7). In four of these (figs. 4, 5, 6, and 8), socket reconstruction was incidental to more extensive repair.

SUMMARY

By using a series of acrylic forms, socket reconstruction with epidermis, both total and subtotal, is expedited and facilitated. Use of the Padgett dermatome assures a uniformly thin graft which is easily handled if the technique outlined above is followed. The middle of the inner arm is favored as the donor site.

NOTES, CASES, INSTRUMENTS

GLAUCOMA FOLLOWING THE INGESTION OF SULFATHIAZOLE*

MILO H. FRITZ, M.D.
Hanover, New Hampshire

AND

MEYER KESERT, M.D.
Chicago

Penicillin has to a large degree supplanted the use of the sulfonamides in the therapy of many bacterial infections, but the use of sulfonamides is still so widespread that the report of an unusual reaction is deemed of interest.

Alvaro¹ in 1943 reviewed the effects other than anti-infectious of the sulfonamide compounds on the human eye. These included: (1) palpebral edema, (2) conjunctivitis, (3) chemosis, (4) scleral reaction, (5) numerous cells in the aqueous and iritis, (6) mydriasis, (7) cataract, (8) changes in the angioscotomas, (9) edema of the retina, (10) reduction of the visual fields, (11) retinal hemorrhages, (12) optic neuritis, (13) undefined or unidentified blurred vision, (14) transient ametropia, (15) changes in accommodation and heterophorias.

No subsequent or previous case reports or reviews at our disposal concerning the effects of the sulfonamide compounds on the human eye add to Alvaro's list. The following case is one of acute congestive glaucoma following the ingestion of sulfathiazole.

CASE REPORT

A white woman, aged 24 years, was seen in the eye clinic of the station hospital, MacDill Field, Tampa, Florida, on the afternoon of April 11, 1945. She said

* From the Eye Clinic of the Station Hospital, MacDill Field, Tampa, Florida.

that itching, light sensitivity, and burning of both eyes had been troublesome since she awakened that morning. Upon questioning, it was discovered that the patient thought she was sensitive to sulfathiazole, having developed red, burning eyes following the ingestion of sulfathiazole prescribed for a sore throat in August, 1944. She had reported this suspected sensitivity to the drug to the medical officer who had seen her in her unit dispensary because of a sore throat on April 10, 1945, but he told her to try the drug again, and that if she proved sensitive it could be discontinued without harm.

Examination showed a mild conjunctivitis in both eyes with a few subconjunctival hemorrhages suggestive of Koch-Weeks infection. Microscopic examination of a stain smear of the conjunctival secretions, however, revealed no organism. Bacterial culture was reported negative after 48 hours. A mild astringent collyrium was prescribed, and the patient was sent back to duty. She was told to stop using the sulfathiazole and report back to the eye clinic in 48 hours.

By the next evening, the pain and redness of the eyes were worse and a severe headache had developed. She again reported to her dispensary. She was sent from the dispensary to the hospital for admission where the chief complaint was recorded as severe headache and pain in both eyes. General physical examination was negative except for the eyes. Temperature, pulse, and respiration were normal. Kahn test of the blood, urinalysis and a complete blood count were normal.

She was seen in the eye clinic early on the morning of April 13th. At this time, her eyes had the typical appearance of acute congestive glaucoma, and this diagnosis was made by Capt. Meyer Kesert. Vision was: O.U., 20/30 correctable to

20/20 with a: O.D., +1.50D. cyl. ax. 105°; O.S., +0.25D. sph. \subset +1.25D. cyl. ax. 75°. There was edema of the eye lids, marked chemosis of the conjunctiva, mild iris edema, small irregular pupils that reacted sluggishly to light and accommodation, normal ocular fundi (as nearly as one could determine through the undilated pupils), and obviously increased intraocular pressure on palpation. Tension at 2:15 p.m. on April 13th was: right eye, 50 mm. (McLean); left eye, 60 mm. One drop of ¼-percent eserine salicylate was placed in each eye every 10 minutes until three doses had been given. At 3:30 p.m., tension of the right was 35 mm., and of the left eye, 22 mm. The considerable relief of the eye pain was accompanied by subsidence of the headache. However, the itching, burning, and general appearance of the eyes remained the same. One drop of ¼-percent eserine salicylate was placed in each eye every hour for 24 hours. On April 14th, tension of the right eye was 38 mm., of the left eye, 35 mm. By April 16th, the chemosis had subsided; the pupils were of normal size and were reacting briskly to light and accommodation. Tension in both eyes was 28 mm. On April 17th tension was: O.D., 24 mm., O.S., 20 mm. The small conjunctival hemorrhages were reduced in number.

Eserine was discontinued on April 18th. From that date until her discharge on April 21st, tension remained 22 mm. in each eye, and the eyes continued to improve until they were considered normal on the day of discharge.

The patient was seen again in the eye clinic two weeks and four weeks following discharge. The tension remained the same and the eyes appeared normal. Because of the severe reaction of this patient's eyes to sulfathiazole, an attempt to reproduce this syndrome by readministration of the drug was not considered justifiable. However, it is felt that this glaucoma was unquestionably initiated by ocular sensitivity to the drug, especially in view of the fact that the patient suffered a much milder reaction in August, 1944. A skin test was not done.

COMMENT AND CONCLUSIONS

A brief review of the effects other than anti-infectious of the sulfonamide compounds on the human eye discloses 15 reactions. A case report of acute congestive glaucoma in both eyes in a patient sensitive to sulfathiazole is reported and added to the list of ocular reactions to these compounds.

DACRYOCYSTORHINOSTOMY

A SIMPLIFIED TECHNIQUE

WILLIAM D. GILL, M.D.
San Antonio, Texas

In the light of our present knowledge, it is generally agreed that the only satisfactory and certain method of restoring the communication between the lacrimal

sac and the nasal cavity, once it has been permanently obstructed, is by surgery. A great many operations have been devised to overcome obstructions in the conducting portion of the lacrimal apparatus. Medical historians note in remote medical annals that crude attempts were made to overcome obstructions to the conducting portion of the lacrimal apparatus, but

the description of such an operation by Toti of Milan, Italy, in 1909 was the beginning of what might aptly be termed the modern surgical approach. Since that time there have been a great many modifications of the operation described. Dupuy-Dutemps, Lagrange, Mosher, and West are a few of the many writers on the subject that could be mentioned.

In the past, these operations have usually been of such great technical complexity that very few surgeons have been able to perform them with facility. By way of emphasis it may be stated that even the most skillful operators have experienced difficulty in suturing the edges of the lacrimal sac to the nasal mucosa, a step in many of the operations. Anyone who has attempted this procedure will realize the difficulties encountered. Many of the operations which have been described for the relief of obstruction in the conducting portion of the lacrimal apparatus represent efforts to simplify the techniques of this procedure, and each has contributed its share to this endeavor. It is with a view to simplifying the procedure further that this report is presented.

For the past 15 years, the writer has been using a method which greatly shortens the time required to perform a dacryocystorhinostomy and, at the same time, overcomes many of the difficult technical phases of the older procedures. The modification has proved to be entirely satisfactory in practice, and it is believed worthy of a trial by all those who are interested in performing such an operation with minimum difficulty and in minimum time.

In performing the operation according to this method, the lacrimal sac is exposed in the usual manner by a curvilinear incision at the inner canthus directly over the lacrimal sac. The incision is carried down to the sac which is exposed and elevated from its bed from the point

where it enters the bony canal upward to the internal canthal ligament. Rarely is it necessary, or advisable, to cut through the internal canthal ligament, but if required for better exposure, this may be done. The sac is severed at the point of entrance into the bony canal and its lower end lifted out of the lacrimal fossa. The remaining portion of the lacrimal passage which is in the bony portion of the canal is destroyed by curettement.

An opening is made through the bone in the depths of the lacrimal fossa with a small chisel or gouge, and a button of bone is removed. The opening may be made round or square, either shape serving equally satisfactorily. The opening should be at least one centimeter in diameter. The mucous membrane of the nose is thus exposed and is cut through by means of a crucial incision. A Graefe cataract knife serves admirably for this purpose. The edges of the nasal mucosa may be trimmed away if desired, but this is an unnecessary refinement.

The lacrimal sac is then slit for a short distance from its bottom on the anterior surface in order to facilitate the introduction of a small (10 or 14 F.) soft rubber catheter. The catheter is transfixed at its upper extremity with a double-armed suture of 00 or 000 plain catgut which is carried into the interior of the lacrimal sac to its apex and out through the skin, first one needle and then the other being passed. The points of emergence are separated by a distance of approximately one-eighth inch. By simultaneous traction on the two sutures, the catheter can then be pulled up into the sac and will remain in position when the sutures are tied. The sac is then pulled sufficiently far down on to the catheter to eliminate any unnecessary folds or wrinkles, and the lower border of the sac is fixed to the side of the catheter with a 00 or 000 plain catgut suture passed through the wall of the

catheter and the lower end of the severed lacrimal sac. More sutures than one may be used if necessary.

The free end of the catheter is then introduced into the opening in the nose and pulled out through the nostril on the same side. As the catheter is pulled into the nose, the lacrimal sac will be pulled with it, and the walls of the sac will come in contact with the nasal mucous membrane. The overlying tissues are closed in the usual manner. If the internal canthal ligament has been cut through, it must be carefully reapproximated by suture. In from three to five days, the sutures which have been holding the catheter in position will have absorbed sufficiently to enable its removal by pulling on the end protruding from the nostril. Each day after the third day, an attempt to remove the catheter is made by gently pulling on its free end. No attempt at forcible removal should be made as the catheter will eventually come away with ease.

Subsequent treatment will minimize the possibility of closure of the newly created channel. It may be necessary to pass lacrimal probes at intervals to maintain patency of the new lacrimo-nasal passage, or exuberant granulations may have to be reduced by cauterants, such as silver nitrate, trichloroacetic acid, or small biting forceps used within the nose at the exact point indicated. Failures in performing this operation will be lessened by

proper selection of the cases for operation. Making a sufficiently large opening through the bony structures into the nose will also contribute to the operation's successful termination.

The procedure herein described has been sufficiently satisfactory in our practice to cause us to believe that it deserves more general adoption. In all instances where we have employed the operation it has been used on adults, most of them in the age group from 40 to 60 years, but we know of no contraindication for its use in younger persons should it be deemed necessary.

Local anesthesia (two-percent novocaine solution, plus adrenalin) is used for the skin and subcutaneous tissues. Deeper infiltration with a small amount of the anesthetic solution will obtain anesthesia of the bony structures. The nasal mucosa is anesthetized by placing a tampon of cotton saturated with a five-percent cocaine hydrochloride solution in front of the anterior tip of the middle turbinate body and allowing it to remain for at least five minutes. We have tried injecting two-percent novocaine into the nasal mucosa instead of the cocaine pack but have found that the ballooning of the mucosa through infiltration increases the surgical difficulties; for this reason, the former procedure is considered preferable.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

February 4, 1946

DR. MAURICE L. WIESELTHIER, *presiding*

TETANUS FOLLOWING OCULAR INJURY

DR. CHARLES LITWIN said that tetanus is very rarely encountered in ophthalmic practice and that one may practice ophthalmology a lifetime without ever seeing a case. However, it is a very serious disease, in spite of the availability of simple and practical methods for its prevention. It should always be borne in mind whenever a fresh severe injury of the eye or adnexa is dealt with. It is more apt to occur after injury to the lids and orbit rather than to the eye itself, especially when the object with which the injury was produced has been in contact with the ground. Dirty wood and earth contain the spores of tetanus bacilli. Diagnosis is easily made by dysphagia, trismus, facial paralysis, and opisthotonos. Prognosis in these cases is very bad. When a severe and dirty case of injury to the orbit comes under treatment, the first precaution is to inject the serum, then cleanse the wound thoroughly and remove any foreign body. In good surgical practice and in war injuries, antitoxin is administered routinely. Sometimes routine precautions may be overlooked with dire consequences as in the case here presented.

D. H., an eight-year old white boy, fell from a one-story roof into a wooden fence on August 16, 1945. He suffered lacerations of the right eyelid, face, and upper lip. These were sutured in a local hos-

pital. Two weeks after the accident, he became irritable, listless, restless, and could not sleep. Tightness of the jaws developed. On September 8th, he suddenly developed paroxysmal contractions of his back muscles, which lasted nearly 10 minutes. Tightness of the jaws was followed by inability to open the mouth and to swallow. At this time, there was a local poliomyelitis epidemic and he was rushed to the county isolation hospital. On admission, there was found to be edema of the right eyelids and a purulent discharge from the conjunctival sac. There was no evidence of any paralysis of the skeletal muscles nor any cranial nerve involvement. There was trismus of both masseter muscles. The face showed spasm of the muscles (*risus sardonius*); there was boardlike rigidity of the neck and back muscles. The abdominal muscles were stiff and on the slightest irritation, such as testing abdominal skin reflexes, contraction of all the trunk muscles set in leading to extreme opisthotonos. Temperature was 101.7°F. Laboratory findings were: urine, 2+ albumin; red blood count, 4,290,000; hemoglobin, 76 percent; white blood count, 5,950; spinal fluid—colorless; cell count, 4; globulin, negative; 68 mg. of sugar; no growth of organism. A diagnosis of tetanus was made.

The treatment consisted of tetanus antitoxin given intravenously in 10 progressive daily doses of 20,000 to 40,000 units, and 120,000 units of penicillin daily for eight days. To reduce hyperalgesia of the skin and reflex irritability, the patient was kept under the constant influence of luminal sodium. A 50-percent magnesium-sulfate solution was given to prevent the spasms of diaphragm and glottis which

occurred four to five times during the first four days he was in the hospital.

After two weeks the condition had improved so that he could open his mouth without difficulty and could swallow easily. The stiffness of the muscles of the trunk and extremities were noticeably less, and his posture and gait were normal. On October 7th he was discharged as recovered but was advised to consult an eye specialist.

On November 8, 1945, he was seen by Dr. Littwin. The upper lid of the right eye was swollen almost shut and there was a thick, purulent discharge from the conjunctiva. A diagnosis of a foreign body in the lid was made, and the next morning, under general anesthesia, an incision was made in the skin and a splinter of wood about $\frac{3}{4}$ by $\frac{1}{4}$ inch was removed. Recovery was uneventful.

FUNDUS FINDING IN LUPUS ERYTHEMATOSUS

DR. JULES LANDOWSKI reported the fundus pathology in two cases of acute lupus erythematosus. Both cases showed striking similarities as to their history and course. The fundi in both patients showed some vascular changes and a varying number of small, round, whitish exudates scattered over the retina in close connection with the retinal vessels. The localization of the fundus lesions in both cases seemed identical, namely in the nerve-fiber layer of the retina. This was suggested by the localization of the exudates in the axilla of dividing vessels or by their extension from one vessel to a neighboring one. In addition some of these exudates had striations which, if there had been but a single lesion, could have been mistaken for a group of medullated nerve fibers. In both cases, one exudate had a small hemorrhage in its center. The

gradual disappearance of the exudates and the reappearance of new ones was also noticed.

In conclusion, it would seem that, if a patient with no evidence of angiospasm and with normal blood pressure presented a clinical picture suggesting the diagnosis of lupus erythematosus, the presence of fundus lesions as described should be considered a valuable factor for this diagnosis.

Discussion. Dr. Ferdinand L. P. Koch said that the drawings of the ocular fundi presented by Dr. Landowski exhibit lesions similar to those in the drawings of the case reported by Dr. William P. McGuire and Dr. Koch last November. (See this Journal, volume 29, number 10, page 1243.) However, they had reason to believe that evidences of vasculitis would be found only in the extreme periphery of the retinas when the more central white exudates were fresh, as is indicated in Dr. Landowski's slides. The location of these exudates is in question. It was not determinable whether they were in the choroid or in the retina. There was a relationship between the relative age of the exudates and the location of the lesions of peripheral vasculitis in that the older the appearance of the exudates, the more toward the optic-nerve head did the vasculitis appear to progress, without regard to whether the venous or arteriolar vasculature of the retina was involved. As a corollary, early vasculitis was observed not only in the retinal periphery near the ora serrata but, also, in the relatively avascular area of the macular region. As loss of nutrition of the retina progressed, primary optic atrophy gradually took place bilaterally.

It is of interest to speculate on the etiology of the protean manifestations that produce or are accompanied by such

fundus findings. Klemperer, Pollack, and Baehr postulated the changes as being occasioned by disturbances of physiology of the collagenous tissue of the body while Stokes, Beerman, and Ingraham suggested, inferentially, that these patients might be victims of a "vasculo-allergic" phenomenon. In any event, it is earnestly hoped that, with the aid of the ophthalmologist, internists will avail themselves of the information that might be theirs ophthalmoscopically in instances that suggest the Libman-Sacks syndrome by whatever name.

REITER'S DISEASE

DR. HERBERT M. KATZIN presented the ophthalmic aspect of a typical case of this disease, which occurs almost exclusively in males, usually without recurrences.

This 42-year-old man had nonmucous, nonbloody diarrhea for 2 to 3 days, was well for three weeks, then had dysuria and pyuria for five days. Conjunctivitis started two days after the urethritis, and a herpetiform rash appeared on the penis. The next day his knee and ankle were swollen and tender. Fever up to 102°F. supervened, and joint involvement spread. His eyes showed marked conjunctivitis and keratitis, with toxic damage to the superficial layers.

Laboratory data included leukocytosis, increased sedimentation rate, and sterile conjunctival cultures. Penicillin and sulfonamides did not affect the course of the disease, but typhoid vaccine was beneficial. After two months the patient was better, but superficial corneal opacities persisted. These disappeared during the next three months.

The etiology seems to be infectious, and a pleuropneumonia-like organism has been recovered from some cases, although not from this one. The eye complications

may include keratitis, iritis, synechiae, complicated cataract, secondary glaucoma, and blindness. The urologic complications may include ascending infections. The joint involvement is quite similar to that seen in rheumatic fever. The overall duration varies between one and six months.

DR. BERT L. VALLEE, in presenting the same case from the internist's viewpoint, said that this disease was not described in the United States until 1941 by Bauer and Engleman, although it had been independently observed in 1916 by Reiter, Fiessinger, and Macfee.

In about two thirds of the cases, the illness is preceded by mild diarrhea of 2 to 3 days, with a low-grade or no fever. There is a symptom-free interval of 3 to 4 weeks, and then suddenly an acute, purulent conjunctivitis and urethritis appear, either one preceding the other by a day or two. A few days later, migratory polyarthritis, resembling that of rheumatic fever, develops. Most frequently the weight-bearing joints of the lower extremities are affected. The conjunctivitis may be complicated by serious eye changes. As a general rule, however, the eye recovers. Colby has described prostatic abscesses, pyelonephritis, and hydronephrosis as complicating urologic features. Chronic arthritis has been described only rarely. Incomplete syndromes have been reported, consisting of urethritis and arthritis without conjunctivitis, and arthritis and conjunctivitis without urethritis. The disease usually runs an uncomplicated course for about 4 to 5 months, although the patient may recover within 3 to 4 weeks. Exacerbations are not uncommon. Hydrarthrosis may occur.

There may be skin lesions of vesicular character, which finally develop a keratotic appearance and are preferentially located over the affected joints, the scrotum, and

penis. These lesions resemble herpes pro-genitalis. The cutaneous manifestation has been described independently as keratosis blennorrhagica without gonorrhea. The lymph nodes and spleen may be transiently enlarged. There is moderate leukocytosis and the sedimentation rate is accelerated. The gonococcus is never found, and the G.C. complement fixation test is negative.

The disease has been reported only in males between the ages of 16 and 45, and the majority of cases occurred in soldiers, aged 20 to 25 years, during World Wars I and II. Until 1941 all reported cases were seen in Europe but, as many recent American papers show, this merely reflects an earlier interest of European physicians in the disease.

Pathologic examinations have usually shown a mild synovitis and fluid of high protein content in the joints. The etiology is obscure. Working independently, Reiter found spirochetes in the blood, and Macfee in the urethra of their patients. Recently Dienes isolated pleuropneumonia-like organisms from the urethra of a male patient who had the forme fruste of Reiter's disease. The morphologic characteristics of the spirochetes and the pleuropneumonia-like organisms show a striking resemblance. The pleuropneumonia-like organisms may be considered as possible etiologic agents in this disease. These organisms, moreover, cause an illness in sheep, agalactia, which in almost all of its manifestations resembles Reiter's disease.

The common chemotherapeutic agents of the sulfonamide and penicillin groups are of no avail. Foreign-protein fever therapy has been found most helpful, but gold therapy has been successfully used by Usseglio and Zaneau. The development of arthritis in mice and rats infected with this organism can be prevented by the

administration of gold salts if given early enough. Gold salts warrant further trial in the management of this disease.

Serologic investigations of patients with Reiter's disease are being carried out by Drs. Wallerstein, Turner, and Vallee.

Discussion. DR. ABRAHAM STRACHSTEIN said that recent American articles on Reiter's disease all emphasize the following three points: (1) Most patients reported are men in the armed services, although the civilian is by no means exempt. (2) The drugs that prove of such great value in urinary and in other infections such as penicillin and the sulfa drugs, seem to have no beneficial effect on the Reiter syndrome. (3) This disease, as previously stated, has thus far failed to reveal any specific germ which presumably acts as its cause.

Dr. Strachstein's patient was a married civilian who came under observation in December, 1944, suffering from Reiter's disease. He had already been treated by his family physician with the drugs mentioned, but without effect. The patient was hospitalized and received an intramuscular injection in the gluteal region of 10 c.c. of milk boiled for 10 minutes. Four hours later, the patient experienced a severe chill and a rise in temperature to 105°F. The fever persisted throughout the night and gradually subsided in the morning at which time the urethral discharge completely disappeared. The conjunctivitis began to clear prior to this injection, but the joint pains persisted. Salicylates were tried for six days with beneficial effect. Another injection of milk was again followed by a severe chill and a rise of temperature. On the following day the patient was agreeably surprised to find that all joint pains had entirely disappeared. The patient was in the hospital for 2½ weeks and left almost completely recovered. He remained under observation for

over 13 months without any recurrences. Typhoid vaccine was not used because isolated fatalities have been reported as resulting from its use.

In a recent article in the *Journal of Urology*, Captain Sargeant, U.S.N., reported 23 cases, in which foreign-protein fever therapy was of definite and distinct value in the treatment of Reiter's syndrome. Dr. Colby reported in 1934 that serious renal complications may arise and that some patients had serious joint deformities and remain ill for many months. He had not used the foreign-protein fever therapy.

Dr. Herbert M. Katzin said the spirochete which Reiter described, and similar organisms that were isolated by Macfee on the West Coast of Africa from patients with this syndrome, exhibited forms that were remarkably similar to the pleomorphic pleuropneumonia-like organisms isolated by the Boston workers. The use of foreign protein was first published in Germany in 1941, although Dr. Gartner had been using it in a case he had been following for some years. Several case reports suggest infection following sexual exposure. In one case, repeated recurrences followed 10 days after sexual intercourse, with a different partner in each instance. In another case, a man developed migratory arthritis and urethritis one week after marriage to a woman who had a vaginal discharge containing pleuropneumonia-like organisms. A previous case at the Mount Sinai Hospital was followed for 16 years with periods of recurrence.

CYCLOPIA

DR. SAMUEL GARTNER reported two cases of cyclops. One is a true single median eye; the other is a fused double eye. Both were located in the center of the forehead. Interesting anomalies were found in them.

The important position of the pigment epithelium was associated with an almost complete absence of choroid, choriocapillaris, and lamina vitrea, and maldevelopment of the overlying retina.

In one case, a misplaced island of retina was found buried in the choroid and sclera in an area where pigment epithelium was lacking. Some proof was found that this anomaly was due to metaplastic development of the pigment epithelium into a retinal type of structure.

Discussion. Dr. Joseph I. Pascal said that he once saw a case of cyclopia in Vienna. In the discussion on that case, a statement was made that the reason for the development of cyclopia is the fact that the anlage for the nose was above the two eyes and failed to descend and separate the two eyes, resulting in the fusion of the anlage of the two eyes into one. Dr. Pascal asked whether this was a plausible cause of the condition in Dr. Gartner's cases.

Dr. Gartner said that there were a great many theories with little proof. The damage of the midline structures that occur in fetal life may be created in animals by X rays and magnesium salts. It is not only due to maldevelopment of the nose, but to all the midline structures.

IRITIS IN BECHTEREW-STRUEMPPELL-PIERRE MARIE DISEASE

DR. F. N. GRAUPNER said that the difficulty in determining the etiologic factors in an acute iritis is well-known. The most common causes are tuberculosis and lues, but there are numerous other general diseases which are often complicated by a metastatic inflammatory process in the iris and ciliary body. The statistics by Gilbert of 500 cases of iritis showed that tuberculosis caused 46 percent; lues, 17 percent; gonorrhea, 3 percent; rheumatism, 3 percent; unknown causes, 18 per-

cent. Guyton and Woods found similar figures.

Belonging to the group of rheumatic diseases, the spondylitis ankylopoietica of Bechterew-Struempell-Pierre Marie is often complicated by an iritis of the recurrent type, according to Dunham and Kautz in 25 percent of all cases. In fact, the relation between spondylitis and iritis is better known to surgeons and orthopedists than to ophthalmologists, so that the ophthalmic literature on this subject is relatively small. The first person to mention the occurrence of an iritis in spondylitis was Fraenkel in 1904; later Fischer, Vontz, Vogt, Kraupa, Kuntz, Marbaix, and Golding reported similar cases.

The spondylitis ankylopoietica is a chronic rheumatic disease. The first to describe this stiffness of the spine were Bechterew, Struempell, and Pierre Marie in 1895. Later with the help of the X ray, the disease was better explored and classified. Today the whole classification of arthritis is still under discussion but, according to Cecil, arthritis is due to five different agents: (1) Infectious arthritis due to gonococcus, staphylococcus, streptococcus, pneumococcus, syphilis, tuberculosis, and other agents. (2) Probable infectious origins, such as rheumatoid arthritis of the adult type, juvenile type (Still's disease), or ankylosing spondylitis. (3) The degenerative joint diseases. (4) Arthritis due to metabolic disturbances as in gout. (5) Neuropathic arthritis (tabes and syringomyelia).

Three cases of iritis due to spondylitis (Bechterew-Struempell-Pierre Marie) were presented by Dr. Graupner. This rheumatoid arthritis produces complete fusion of the vertebra and extreme stiffness of the spine. The iritis is of a recurrent type characterized by a gelatinous, fast-disappearing exudate in the anterior

chamber, fine dustlike precipitates, and synechiae of the pigment leaf of the iris. This diffuse, metastatic iritis is in contrast to the iritis in such granulomatous diseases as tuberculosis and lues which are more severe, involve the ciliary body, and are of longer duration. Since the iritis is a sign of rheumatoid activity in the body, treatment should be directed against both the iritis and the underlying rheumatic disease.

Discussion. Dr. Milton Berliner said he saw the first case described by Dr. Graupner. Since that time, he has observed three additional cases which seemed to fall within this category. In each instance his attention was arrested by the fact that these patients had difficulty in placing their chins on the chin-rest of the biomicroscope. In two of the cases, there was a definite history of a chronic Neisserian infection. Dr. Graupner mentioned something about the clinical differential diagnosis between iritis of granulomatous and nongranulomatous origin, but Dr. Berliner did not believe that a differential diagnosis is always possible, since even in the granulomatous form, some mild, abortive, exudative cases may occur.

Dr. Daniel Rolett described a dentist who had to sleep outdoors a great deal while in the Army. Before entering the Army he was in perfect health. Soon after discharge from the Army because of poor health—his case was diagnosed at the Mayo Clinic as one of spondylitis deformans—he developed photophobia, pain, and blurred vision in the right eye. These persisted with periods of remission. One year after discharge from the Army, he presented recurrent iritis of the right eye. A mild ciliary infection was present with minute deposits on the posterior corneal surface, a swollen and edematous iris, but no evidence of adhesions. The patient did

not give any history of previous eye disease, nor did he mention that there was anything wrong with him physically. The first inkling of the disease was discovered when the patient was unable to adjust his neck to the chin support of the slitlamp and a peculiar limp was noted which was attributed by the patient to a "weak hip joint." X-ray studies of the spine confirmed the diagnosis of spondylitis deformans. The patient refused to take atropine locally as it would interfere with his work as a dentist. Therefore, no local treatment was administered with the exception of hot packs to the eye once daily. Atophan (7 gr.) was given twice daily. On the third day, remarkable improvement in the eye was noted with absence of any inflammation. Treatment was stopped.

Comdr. Arthur A. Knapp said that he had seen many arthritic conditions in the arthritis clinic in the Hospital for Special Surgery over a period of years. They included various types of arthritis, some with spondylitis. The majority of individuals never suffer from any external ocular disease. It is rare to see iritis or any external ocular disease in arthritis.

RUBEOSIS IRIDIS

DR. JACK V. LISMAN reported a case of rubeosis iridis in a diabetic patient. The diabetes was of long standing, mild, and easily controlled.

The patient presented the typical picture of rubeosis in the right eye. There was a red ring of small capillaries surrounding the pupil with several vessels running peripherally in to the angle. The tension was extremely high and responded very poorly to miotics. Perception of light was soon lost. The eye was very painful, with the pain controlled somewhat by atropine. Because of the pain, the eye was

finally enucleated. Examination of the enucleated eye revealed a newly formed membrane on the surface of the iris extending into the pupillary area; the angle was obliterated by synechiae; the optic nerve was deeply cupped; and numerous hemorrhages and exudates were present in the retina.

Three months after the onset of rubeosis in the right eye, the left eye became painful, with an elevated tension and the picture of rubeosis iridis. The tension was controlled for a period of two weeks by a posterior-scleral trephine; the operation did not result in any significant bleeding. A Lagrange sclerectomy was performed when the tension began to rise. The tension remained controlled for a while and then there were repeated hemorrhages in the anterior chamber with elevated tension and ultimate blindness.

The glaucoma associated with rubeosis iridis responds better to mydriatics than to miotics. This is probably due to a mechanical squeezing out of blood from the capillaries on the iris as the pupil dilates.

Discussion. Dr. Ernst Waldstein said that, considering the great number of diabetic patients, it is certainly surprising that rubeosis iridis is such a rare affection. It is the more surprising since, as the late Dr. Agatston emphasized, pathologic changes in the retinal veins are so common that we might safely say they are practically always present in all the more advanced diabetic cases. Still rarer, of course, is the bilateral occurrence of iris rubeosis. Among other symptoms associated with rubeosis of the iris is a certain ruddiness of the face, especially of the forehead, and anomalies in the capillaries of the nailbed. Anent Dr. Lisman's recommendation of atropine in secondary glaucoma of rubeosis patients, it would seem

a much safer procedure to use 10-percent neosynephrine.

DENTAL AFFECTIONS IN OCULAR DISORDERS

DR. DANIEL KRAVITZ presented a paper on this subject which was published in this Journal, volume 29, number 9, September, 1946.

Leon H. Ehrlich,

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

February 12, 1946

DR. J. WESLEY MCKINNEY, *presiding*

CHOROIDAL DETACHMENT FOLLOWING OPERATION FOR RETINAL DETACHMENT

DR. J. WESLEY MCKINNEY reported the case of Mr. W. H. W., aged 68 years, who was first seen in November, 1945. The right eye had been blind for 14 years as a result of uveitis. There had been several attacks of anterior uveitis in the left eye. Three weeks before he had noticed a black streak before the left eye which had spread to involve almost the entire field of vision.

Examination revealed no light perception in the right eye and 20/400 vision in the left. The tension in the left eye was normal. There was an aqueous flare but no cells in the anterior chamber. The iris was bound down by a few fine posterior synechiae. The vitreous was very hazy. The upper two thirds of the retina was detached to the disc and including the macula. There was a large horseshoe tear at the 12:30-o'clock position and a larger wedge-shaped tear at the 3-o'clock position. Operation was refused at the time, but the patient returned in a few days with the entire retina detached. He was

operated upon December 5, 1945. The postoperative course was uneventful. Both tears were apparently sealed and the retina reattached.

He returned on January 14, 1946, stating that he had suddenly gone blind again two days previously. The retina was everywhere detached except in the upper one fourth. The upper tear was well sealed but the temporal tear was not. He refused reoperation until January 29th when diathermy was again applied to the region of the temporal tear. At the first dressing, a large choroidal detachment was seen nasally which progressed to obscure a view of the disc. The choroidal detachment had gradually subsided and apparently the retina was reattached, although visibility of the retina was not, as yet, too good.

POSTHERPETIC NEURALGIA

DR. J. WESLEY MCKINNEY reported the case of Mr. I. W. W., aged 25 years, who gave the history of having blisters over the left side of the forehead with severe pain one month before. The eye was very red for three weeks. The blisters were present for only one week. Examination showed the skin over the left side of the forehead and back into the hair to be red, slightly elevated, indurated, and hyperesthetic, corresponding to the distribution of the ophthalmic division of the fifth nerve. The nasociliary branch was not involved. The left eye was not inflamed. Corneal anesthesia was marked. There were three superficial opacities of the cornea, temporally. The eye was otherwise normal. The condition was considered to be postherpetic neuralgia. Eucupine-procaine with adrenalin (0.5 c.c.) was injected into the supraorbital nerve. He was partially relieved by this injection. Close questioning brought out the fact that the remaining pain was more temporally, so eucupine-procaine (0.5

c.c.) was injected into the region of the lacrimal nerve. The next day there remained a small area of pain in the temple which corresponded to the area of the zygomaticotemporal nerve. When this nerve was injected, the pain was completely controlled. Ten days later he had had no return of pain. The skin of the involved area seemed normal and was not hyperesthetic.

ANOMALIES OF ACCOMMODATION

DR. PHILIP MERIWETHER LEWIS reported two cases with unusual accommodative findings.

Case 1. F. H., a white man, aged 30 years, complained of being unable to read ordinary print except for a very short period. He had noticed this condition for the past two or three months and thought it was gradually getting worse. Vision was 20/20 and J1 in each eye but his accommodation measured only 2.5 diopters separately and 3 diopters with both eyes together. No other abnormality was discovered. Manifest and homatropine refraction showed only a slight hyperopia, +0.50D. sph., O.U. Except for being a thin and rather frail looking individual, the man's physical examination and laboratory findings were negative. He had not been ill. His occupation as a printer required rather close confinement and exposure to considerable fumes from molten type metal. He was given a +1 sph. for reading, rather large doses of mixed vitamins, and suggestions for a better diet. He took a three weeks' vacation and an increased amount of outdoor exercise. After two months, his accommodation had increased to 4.5 diopters and reading was more comfortable.

Case 2. Mrs. R. E., a white woman aged 48 years, complained that her eyes tired and watered excessively on attempting to read. She had worn glasses for the past four years, the present ones being

about three years old. Both times she had been fitted with bifocals. She was wearing: O.D., +0.50D. sph. \subset +0.25D. cyl. ax. 180°; O.S., +25D. sph. \subset +0.75D. cyl. ax. 65°; with a +2 added for near. Except for a slight congestion of the conjunctiva of both eyes, examination was negative. Uncorrected vision was O.D., 20/70; O.S., 20/50. By manifest refraction, she measured: O.D., +1D. sph. \subset +75D. cyl. ax. 180° = 20/30; O.S., +25D. sph. \subset +75D. cyl. ax. 20° = 20/30. With this distance correction, she could read J1 in to 11 cm. from the anterior focal plane, which is equivalent to 9 diopters of accommodation. Measured separately the accommodation was slightly greater in the left than the right eye. No abnormality of the lenses was found to explain the unusually high accommodation. The distance refraction only was ordered.

INTERSTITIAL KERATITIS TREATED WITH PENICILLIN PACKS

DR. HAROLD KUSHI (by invitation) presented a case of syphilitic interstitial keratitis which was treated with penicillin packs.

Miss P. J. B., a white girl aged 12 years, was first seen on January 15, 1946, complaining of lacrimation, photophobia, redness, and blurring of vision which began about six months before. She had been treated by several doctors including an "eye specialist" with no apparent improvement. Examination on entry revealed the following:

Visual acuity in the right eye was 20/65; in the left eye, 20/30. Tension in both eyes was 25 mm. Hg (Schiotz). There was marked photophobia and lacrimation associated with conjunctival and ciliary injections. Both corneas showed numerous opacities and extensive vascularization. The pupil of the left eye was well dilated; that of the right eye was

contracted. Numerous keratitic precipitates were seen in the right eye with the slitlamp; none in the left eye. The fundus examination of the left eye revealed medullated nerve fibers adjacent to the disc on the nasal side. The fundus of the right eye was not visible. The patient's mouth revealed typical Hutchinson's teeth. The Wassermann test reaction was +4. The patient was admitted to the hospital and penicillin-impregnated cotton packs were applied to the lower cul-de-sac of both eyes for a period of two hours, twice a day. The concentration of the penicillin solution used was 20,000 units per c.c., and $\frac{1}{4}$ c.c. (5,000 units) was used for each application to each eye. Locally, atropine ointment was also used. She was given three injections of milk intramuscularly, two injections of bismuth, and two of mapharsen. Improvement in the form of absence of lacrimation and photophobia was noted 24 hours after the initiation of penicillin packs and atropine. Improvement was progressive and on discharge, 10 days after entry, both eyes showed only slight conjunctival and ciliary injections.

RECURRENT VITREOUS HEMORRHAGE (EALE'S DISEASE)

DR. HAROLD KUSHI (by invitation) presented a case of recurrent vitreous hemorrhage in a young man.

Mr. J. M., aged 27 years, was first seen in the Memphis Eye, Ear, Nose, and Throat Clinic on January 21, 1946, complaining of partial loss of vision in his left eye. Approximately three weeks prior to entry the patient had a sudden spontaneous loss of vision in his left eye followed by a partial return of vision after the use of "drops" which dilated his pupil. Vision again became blurry a week before entry. The patient had been blind in his right eye for the past five years. No history of injury to either eye was ob-

tainable. Examination on entry revealed the following:

Visual acuity of the right eye was light perception with no projection; in the left eye, 18/200. Tension in both eyes was 23 mm. Hg (Schiotz). There was a mature cataract in the right eye. The conjunctiva, cornea, and iris of both eyes appeared normal. Fundus examination of the left eye revealed a massive hemorrhage in the vitreous superimposed upon several white proliferative-type membranes. A tuberculin test gave a +2 reaction. X-ray studies of the chest revealed tubercular hilar glands. The Wassermann test was negative; so was the urinalysis. Atropine ointment was applied locally and potassium iodide was given internally. Visual acuity improved from 18/200 to 20/100. The patient was discharged from the hospital and given instructions for a series of old tuberculin treatments by his family doctor.

CHICAGO OPHTHALMOLOGICAL SOCIETY

February 18, 1946

PETER C. KRONFELD, *president*

CLINICAL PROGRAM

(Presented by the Department of Ophthalmology, The University of Chicago)

ENDOTHELIAL DYSTROPHY WITH COMPLICATED CATARACTS

DR. MAURICE J. DRELL presented V. D., a 43-year-old white man, whose case has been followed at The University of Chicago Eye Clinic since November, 1942, at which time he had corrected vision of 20/30 in each eye, a bilateral mild endothelial dystrophy, and immature subcapsular cataracts. The corrected vision dropped to 20/70 in each eye (April, 1944), and 20/100 in the right eye and

20/200 in the left eye (September, 1945). He returned in December, 1945, with a story of rather rapid loss of vision during the preceding weeks; unaided vision was finger counting at three feet in the right eye; barely 20/200 in the left. The dystrophy was unchanged. The left lens was mature and the right lens, almost mature. A right combined extracapsular extraction was done in December, 1945, with uneventful healing. On February 7, 1946, corrected right vision was 20/20 and 6-point printer's type.

BLOOD STAINING OF CORNEA

DR. MARTIN P. WOOLF presented the case of A. D. H., an 11-year-old white boy, who was seen in University of Chicago Clinics, October, 1945, with a history of having been struck on the right eye four months previously. The eye was not perforated but there was a history of two anterior-chamber hemorrhages following the injury. The anterior chamber was irrigated two weeks post injury.

Examination revealed a 7 to 10 degree divergence in the right eye. Light and color perception were present. There was a horizontal linear scar on the cornea of the right eye at the 12-o'clock position, a result of surgery. The posterior surface of the entire right cornea was covered by a greenish-brown, dense opacity except for a clear zone of about 1 to 2 mm. around the entire limbus. Under slitlamp examination the greenish-brown opacity had a ground-glass appearance which covered the entire posterior surface of the cornea except for the clear zone previously mentioned. There was a surgical coloboma of the iris at the 10-o'clock position. There were numerous brown granules on the iris.

Treatment was deferred, awaiting the degree of resorption. Later a keratoplasty may be considered.

GENERALIZED SARCOIDOSIS

DR. MARTIN P. WOOLF presented J. L. W., 27-year-old colored man who was seen by Dr. W. Jones at Provident Hospital and referred to The University of Chicago Clinics for further study. The patient was seen December, 1945, with a history of painful swelling of the left eyelids and injection of the left sclera in 1943. About one week after onset, several nodules, which are still present, appeared on each upper eyelid. In 1944, painless pea-sized nodules appeared on the skin of the neck, arms, groins, and legs. These are still present.

In April, 1945, a similar episode involved the patient's right eyelid and sclera more severely than the left eye had been involved. The pupil of the left eye was smaller than that of the right. When he was seen in September, 1945, his vision was: right eye, 20/20; left eye, 20/25. Both eyes were painful and red.

When seen again, in November, 1945, his vision was: right eye, 20/25; left eye, 20/160. Lesions on the left iris resembled those on the skin. The left pupil was small, irregular, and fixed. Red reflex in the left eye was very dull. The discs could not be seen. Attempted dilatation of the pupil was unsuccessful.

Visual acuity has remained unchanged, as have the lid, subconjunctival, and pericorneal infiltration, which are presumably sarcoidal. There are two intrairidic, gray-white, translucent nodules in the left eye. A biopsy of a shoulder nodule reveals sarcoid. X-ray studies of the fingers, toes, and chest are confirmatory.

BILATERAL MILD ENDOTHELIAL DYSTROPHY COMPLICATED BY UVEITIS WITH SECONDARY GLAUCOMA

DR. A. W. FELDMAN reviewed the case of O. N., a 66-year-old white man who presented himself at The University of

Chicago Eye Clinic on February 12, 1946, with the complaint of poor left vision of one week's duration. The patient stated that his eye had become "a little sore" about February 1, 1946. He paid little attention to this until, upon awakening one morning about a week later, he found a marked reduction of vision in the left eye. Compresses failed to give relief. Past and family history were noncontributory except for nocturia of several years' duration.

Examination revealed: aided vision in the right eye 20/16-3; aided vision in the left eye, finger counting at two feet. The left eye revealed a steamy cornea with a central film of grossly visible precipitates about 4 mm. in diameter. The right eye appeared grossly normal. Biomicroscopy revealed a guttate cornea of the right eye with scattered pigmented precipitates. The left cornea was also guttate and was carpeted with large, fatty, confluent precipitates. The left anterior chamber showed a faint aqueous ray, but no cells nor lens detail could be made out through the thick layer of precipitates. Tension readings were: R.E., 15 mm. Hg (Schiotz); L.E., 33 mm. Bjerrum fields showed a concentric constriction of the left field of vision to 20° with a 3/1,000 white target. Blood count, urinalysis, serology, agglutination tests, skin tests with Frei antigen, old tuberculin, and brucellergen were noncontributory, as were chest fluoroscopy and sedimentation rate.

Under heat and atropine therapy tension of the left eye has been controlled; aided vision in the left eye is 20/70. Diagnosis was: (1) Bilateral, mild endothelial dystrophy. (2) Left eye: uveitis with secondary glaucoma.

BILATERAL RETINAL AND MACULAR DYSTROPHY

DR. A. W. FELDMAN presented M. A. S.,

a 22-year-old white man, who came to The University of Chicago Eye Clinic with a complaint of "blurring of central vision" of six years' duration, temporarily improved with glasses. The history further revealed that except for an older sister with some eye trouble of unknown nature, no one else in the family had any eye difficulties.

Examination showed vision to be: O.U., 10/200 improved with his glasses to 20/200. The following pathologic conditions involved both macular regions. The macula was a red-brown color surrounded by a ring of bright red reflexes which was in turn surrounded by a brown granular zone. About two prism diopters from the fovea, there was another ring consisting of small, discrete, rather uniform, white opacities. A few such opacities were scattered in the periphery. Laboratory findings were non-contributory. Bjerrum fields revealed absolute central scotomas, 5 to 8 degrees in diameter. Examination of the patient's twin sister failed to reveal any pathologic condition of the fundus. Diagnosis was congenital retinal and macular dystrophy of the right and left eyes, etiology undetermined.

With telescopic lenses, the patient was able to see 14-point type with the right eye and 12-point, with the left eye. There was no appreciable improvement for distance.

PROBABLE TOXOPLASMAL CHORIORETINITIS

DR. F. S. RYERSON presented Miss P. M., aged 19 years, who was first seen at the clinic in January, 1946, with the complaint of seeing spots before her right eye. At the age of seven, she had told her mother that she could see only half of her. An oculist was consulted, and he informed the parents that vision in the left eye would not improve. This incident was followed by a period of approximately nine years of apparent inactivity of the eye disease. She saw an oculist in March,

1945, because of cloudy vision and floating spots. He noted vitreous exudates in the right eye and a large area of chorioretinitis at the 6-o'clock position in the periphery; this lesion appeared to be quiescent. The left eye revealed a quiescent chorioretinitic lesion involving the macular area. General examination, including X-ray studies of the teeth and sinuses, was negative. The patient was placed on a regime of proteolac injections, salicylates, and potassium iodide. At the same time, under the care of another physician, the patient was being treated with autogenous vaccines prepared from the feces. There was some improvement in vision of the right eye followed by an exacerbation in November, 1945.

When the patient was first seen at the clinic, vision was: O.D., 20/30; O.S., 20/200. Examination of the fundus revealed numerous floaters in the right vitreous and a veil-like haze which obscured fundus detail. A large, active chorioretinitic lesion was apparent about eight prism diopters below the right disc. Vitreous of the left eye was relatively clear. There was an old, inactive chorioretinitic scar with pigment disturbances on the left eye about 2 to 3 prism diopters in size and involving the macular area. Laboratory tests revealed normal hemogram and negative agglutinations. The skin tests with 1:1,000 old tuberculin and the Frei test were negative.

The patient was placed on vasodilators. Subsequently the right vitreous cleared slightly. On January 30, 1946, a 2+ aqueous ray and 15 to 20 cells were noted on slitlamp examination of the right eye. The patient was placed on a regime of 50 mg. of atabrine three times daily on alternate weeks. Subsequently, the activity in the right eye increased and again subsided somewhat. Central fields taken before the most recent episode revealed only

an absolute central scotoma on the left. Tentatively, the diagnosis was toxoplasmosis, awaiting further immunologic studies.

PROBABLE CONGLOMERATE TUBERCULE

DR. C. KEITH BARNES presented Mrs. C. J., a 37-year-old white woman, who stated that her vision had been quite normal until January, 1944, when she suddenly became aware of image distortion in the left eye. Vision deteriorated over a period of one year to about 20/200, O.U., and dropped in one more month to hand movements at two feet. She was seen by several specialists, but the process continued relentlessly. Subjective symptoms had been negligible throughout.

Examination revealed the left macular area to be occupied by a protruding, rounded, gray-white mass surrounded by a zone of radiating retinal traction folds. Two small, blurred, dull-white satellite patches were nearby, and the entire central retina showed pallor and edema. Temporally, a crescent of flat, blurred exudates could be seen, as well as two shrinking bands of proliferated scar tissue.

She received skin tests of tuberculin, brucellergin, and Frei vaccine; X-ray studies of the sinuses and chest; two hemograms and urinalyses; nose and throat cultures, sedimentation rate, serologic tests for lues, agglutination tests for typhoid, paratyphoids A and B, brucellosis, and proteus O19, as well as hourly temperature observations. The tests were noncontributory. Considerable dental work was needed and done. General medical and ear, nose, and throat consultations were noncontributory.

On the basis of the lesion's appearance and clinical course, it was thought to be a conglomerate tubercle of the choroid. The weaker dilutions of tuberculin gave negative skin tests. Lymph-gland biopsy, had

not been done, as the glands have only recently become palpable at all. The lesion seemed to be much shrunken and whiter. It was apparently subsiding into quiescence. Treatment has been supportive. Visual fields reveal a stationary, central scotoma of the left eye.

BILATERAL OPTIC NEURITIS

DR. MAURICE J. DRELL presented J. M., an eight-year-old white boy, who was first seen on December 3, 1945, with a history of pain in the eyes six days previously, rapidly followed by a total loss of vision in the right eye and great loss of vision in the left eye, together with subsidence of pain. Vision was: no light perception in the right eye; 5/200, left eye. He was able to identify yellow and blue correctly but said that red was purple. The right pupil did not react to light directly, although it did consensually; the left pupil reacted to light directly, but not consensually; both pupils were dilated and reacted well in convergence. The discs showed two diopters of elevation, peripapillary retinal rucking, distended veins, and grayish maculas. The left field showed extreme constriction, relatively more so nasally than temporally.

On December 5th, the right eye was able to distinguish a flashlight stimulus but not an ophthalmoscopic light. Vision in the left eye was 8/200. Both pupils reacted. The right disc was elevated one diopter; the left, three diopters. Fields showed a bilateral, predominantly nasal, loss. Vasodilators by mouth were prescribed.

On December 11th, vision was about 8/200, O.U., and both discs were still elevated, although the right disc was pale and the right retinal veins no longer engorged. The fields had widened out, with bilateral central scotomas. On December 17th, the right disc was flat and pale, and the left disc was elevated, although mini-

mally, and it was still slightly hyperemic.

Since the patient's vision was 8/200, he was started in sight-saving classes after the Christmas holidays. On January 24, 1946, however, his vision in the right eye was 20/20 and 4-point type; in the left eye, 20/100 and 9-point type. Both discs were pale, the left more so than the right, and Bjerrum fields showed only questionable peripheral constriction on the left. On February 7, 1946, vision was: R.E., 20/20 and 3-point type; L.E., 20/50 and 4-point type (slowly). The boy has been returned to regular school.

A physical examination, neurologic and ear, nose, and throat work up, urinalysis, complete blood count, serology, tuberculin test, throat cultures, X-ray studies of the skull, optic foramina, and of the long bones for lead were all negative insofar as revealing any possible etiology for the case. This case probably fits into the category of optic neuritis of unclassified type reported by Clay and Baird before the Section on Ophthalmology at the 1937 A.M.A. convention.

PARKES-WEBER-OSLER-DIMITRI SYNDROME

DR. C. KEITH BARNES presented the case of Miss M. H. This 41-year-old white woman had an extensive history, including pulmonary tuberculosis with a right thoracoplasty which was probably coincidental and had no relation to her ophthalmic problem. The history also included many years of violent and recurrent digestive upsets, variously diagnosed as food poisoning, bilious attacks, ptomaine poisoning, and so forth. She had had an episode of convulsions at the age of eight. She had been troubled with headaches, all her life. These had been particularly severe during the past 16 years. The headaches were accompanied by brilliantly colored light sensations, fortification spectra, and brief blacked-out epi-

sodes, and they occurred not infrequently during sleep as well as while she was awake.

Examination revealed a nevus flammeus of the left forehead and scalp, a faint intracranial calcification in the left occipital region, and a right homonymous, inferior quadrant field defect. There was also numbness of the right foot. In 1930, two oval yellow patches of uncertain nature were seen in the periphery of the left fundus; they had not been seen again. The patient is mentally alert but says her memory has been poor the past 15 years. The Schiøtz tenometer recordings were normal.

There has been no examination of the patient's relatives, but she reports that one cousin has a small birthmark over the inner canthus of one eye. Following a neurologic examination, her condition was diagnosed as a case of Parkes-Weber-Osler-Dimitri Syndrome, a condition closely related to the better known phacomias. The patient has received occipital irradiation, resulting in this epilation, with little relief. She routinely wears "Covermark" to conceal the port-wine stain, and is able to carry on her secretarial work.

DIABETES WITH CATARACT, RETINOPATHY, AND HEMORRHAGIC GLAUCOMA

DR. BARBARA SPIRO presented Mrs. T. Z., a 55-year-old white housewife, who was first seen in The University of Chicago Eye Clinic in consultation with the diabetic service. She had had poor vision in the left eye for the past two years with no other ocular symptoms; vision in the left eye was good. Although she had been on insulin therapy and a diabetic diet for only a few days prior to eye examination, the patient had known that she had diabetes for about 12 years.

Examination revealed her vision to be R.E., hand movements at eight feet; L.E., 20/25.

The lens of the right eye exhibited the picture of a mature cataract. The fundus could not be visualized through the dense lens. The left lens was fairly clear, but the left fundus revealed a moderate diabetic retinopathy.

Since vision of the left eye decreased fairly rapidly to 20/100 because of a developing cataract, a right extracapsular cataract extraction was performed about one year after the patient was first seen in the Eye Clinic. The diabetes was well-controlled and patient's postoperative course was uneventful. Her aided vision, postoperatively, was 20/200, this comparatively poor vision being due to a considerable diabetic retinopathy.

The patient was well satisfied with this modest result and her course was uneventful until she developed a 3 mm. hyphema six months after the cataract extraction. In spite of large amounts of vitamins and bed rest, the hyphema did not decrease. After about two months, tension in the right eye registered 28 mm. Hg in spite of miotics. The patient experienced no ocular pain or headache at any time. After about two months' duration of the hyphema, rubeosis iridis developed in addition to the hyphema; slowly the blood became organized and the iris lost its normal pattern. The patient now has the full picture of a hemorrhagic, but painless, glaucoma associated with diabetes.

CORNEAL DYSTROPHY

DR. BYRON L. GIFFORD presented a case of Dystrophia Corneal Granulosa (Buckler's, 1938; formerly Fleischer's type). The patient, Mrs. F. I., aged 27 years, was seen in the clinic October, 1945, complaining of moderate, but relatively constant, pain in the left eye for the past six months, and similar pain in the right eye for the past two months, bilateral tearing for bright lights, and occasional

frontal headache after reading. Corrected vision was: R.E., 20/20; L.E., 20/13.

Slitlamp examination showed the corneas of both eyes to have numerous, scattered, white bread-crumble opacities. The irregular-shaped opacities were estimated to be about 0.1 mm. to 0.4 mm. in diameter. They were well distributed over the central cornea, but there was an uninvolved peripheral ring of clear cornea measuring 2 mm. in width. The bodies of the opacities appeared to be flattened against Bowman's membrane, but the fine fingerlike projections involved the anterior one third of the stroma. There was a marked loss of corneal sensitivity. No corneal vascularization was seen. Other examinations of the eyes revealed no abnormal findings. Four brothers, two sisters, father, and mother had no history of eye disease. Some of the eye symptoms were relieved by a change in correction.

SCIENTIFIC PROGRAM

RETINAL VASCULAR LESIONS

DR. JONAS A. FRIEDENWALD, Baltimore, Maryland, gave the second annual Sanford R. Gifford Memorial Lecture. His subject was: "Disease Processes versus Disease Pictures in the Interpretation of Retinal Vascular Lesions."

Robert Von der Heydt.

COLLEGE OF PHYSICIANS OF PHILADELPHIA

SECTION ON OPHTHALMOLOGY

February 21, 1946

DR. BURTON CHANCE, *chairman*

FLUORESCENT COLORS IN TANGENT SCREEN EXAMINATION

DR. JACOB B. FELDMAN and HAROLD J. ABRAHAMS, PH.D. (by invitation) presented a paper on this subject.

COMPLETE UNILATERAL OPHTHALMOPL GIA DUE TO PRIMARY CARCINOMA OF THE SPHENOID SINUS

DR. I. S. TASSMAN presented a case of complete unilateral ophthalmoplegia due to primary carcinoma of the sphenoid (orbital apex—sphenoid fissure syndrome) with involvement of the structures passing through the sphenoid fissure and optic canal and including the right ethmoid and right maxillary sinus and without involvement of the inner walls of the orbit.

The patient, a 58-year-old woman with a history of having had severe headaches for several years, was admitted to the medical ward at Mt. Sinai Hospital for study. Several days before admission she had marked epistaxis. She suddenly lost vision in the right eye four days after admission. Within two days there was complete ophthalmoplegia and ptosis of the right eye.

After complete studies and an exploration of the right orbit, a review of the X-ray films revealed a destructive lesion involving the sphenoid sinus. An extensive right sphenoidectomy, ethmoidectomy, and antrotomy through the nasal approach was performed.

Histologically the tissues from sphenoid sinus, ethmoid, antrum, and nasal mucosa were all reported as having a definite malignancy resembling carcinoma. Although primary malignancy of the sphenoid sinus is rare with only about 42 cases having been reported, in this case the carcinoma must be seriously considered as primary in the sphenoid sinus.

Most cases recorded in the past were incomplete in their manifestations and described under various names, the most common of which was orbital apex-sphenoid fissure syndrome. The writer feels the name of the syndrome should be more specific and descriptive of the symptom complex, which results from

a morbid process involving the sphenoid fissure and the optic canal with the structures they contain; hence, the name, "S-O syndrome with complete ophthalmoplegia."

DR. BENJAMIN H. SHUSTER gave further details of this case. He said that his first association with this patient was when he made a routine ear, nose, and throat examination at which time he found nothing of interest. He saw the patient again a week later during an episode of epistaxis. There was nothing at this time to indicate anything but a local area of bleeding. The nose was packed and the bleeding controlled. One week later, bleeding from the nose recurred, and he again saw the patient. At this time there was also present a marked paralysis of the ocular muscles. However, there was some reaction of the pupil to light.

Not being familiar with the specific nomenclature of the sphenoid-fissure syndrome, he had groped for an anatomic diagnosis. The vestibular (caloric) test did not reveal any sign of an intracranial lesion. Aside from the ocular immobilization, there were no signs of any mass in the orbit. The presence of the pupillary reaction to light pointed against the possibility of a brain-stem lesion which would also have to be extensive to involve the number of nerves concerned. There were no systemic signs of cavernous-sinus thrombosis. Edema and ecchymosis which are found in this condition were not present. The situation seemed to resolve itself into a possible small hemorrhage at the apex of the orbit incompletely compressing the nerves, or a growth in the sphenoid sinus encroaching slowly upon the contents of the cavernous sinus adjacent to its lateral wall. This could compress the nerves and yet permit some venous blood to pass through preventing the occurrence of edema and ecchymosis. A specific request was made for orbit and

sphenoid sinus X-ray films. These were misinterpreted, and the sphenoid was pronounced negative.

It was decided to explore the orbit through an incision at its medial boundary. If an erosion was found on the nasal wall, it could be followed through. No such break was found, and in view of the negative sphenoid-sinus report, no further search was made. The possibility of an intracranial lesion had to be considered. Shortly after the operation, the films were again studied and the conclusion was reached that the sphenoid as well as other sinuses were involved. Accordingly, it was decided to research the wound with the idea of breaking through to the sinuses, and an attempt to reach the sinuses, nasally, was first made.

When a sphenoid probe was introduced, there was immediate indication that the posterior sphenoid bony wall was destroyed. The nose at first appeared to be normal, but after breaking down the bony covering, a mass of malignant-appearing tissue was seen in the sphenoid, ethmoid, and maxillary sinuses. Microscopic study of this tissue showed it to be malignant. He believed that Dr. Tassman was correct in his contention that the primary growth was in the sphenoid. The vague headache and the bulk of the mass in the sphenoid pointed in that direction. Those who have seen some of the cases of malignancy of the antrum will agree that, in the length of time the condition existed in this patient, the orbit would have been invaded much sooner and not in a fashion of involving the nerves, but rather of involving the entire intraorbital contents.

The orbital incision employed in this case was routine for extranasal exenteration of the sinuses. It afforded a very satisfactory exposure of the orbit in its floor, median wall, and roof.

DR. HENRY A. SHENKIN said that the neurosurgeon's interest in this patient

rested in the possibility of an intracranial lesion producing this syndrome, particularly a tumor of the sphenoidal ridge. Unquestionably, the outstanding point in the differential diagnosis was the fact that a sphenoidal-ridge meningioma is a very slow-growing lesion, the symptomatology being gradually progressive over a period of years or, at least, for many months. For the same reason, the external ocular muscle involvement is rarely complete, the slow-growing lesion distorting but not completely interrupting the nerves passing through that region.

There may be blindness from a sphenoidal meningioma. He believed that at least 25 percent of cases have severely impaired vision, but this will usually be accompanied by primary optic atrophy, resulting from the length of time the optic nerve has been under pressure. Carcinoma of the sinuses may cause exophthalmos, which is also an outstanding feature of sphenoidal-ridge meningioma. X-ray studies would reveal hyperostosis of the orbital roof and of the sphenoidal wings in the latter. In such exophthalmos, the optic bulb would tend to be depressed due to exostosis of the orbital roof. Malignancy of the sinuses will be accompanied by erosion of the bones of the orbital cavity, and bones nearby.

DR. I. S. TASSMAN (in closing) said that cases of this kind were very unusual. This patient came to his attention because of the ocular condition while she was on the medical service under treatment for vascular hypertension. As Dr. Shuster pointed out, it was logical to enter the orbit on the medial aspect so that it would be easy to enter the sinuses at the same time if this appeared to be indicated. Strangely enough the orbital walls were found to be perfectly normal, and the nasal sinuses gave no evidences of the presence of any disease.

In spite of this, he strongly suspected

trouble in the sinuses even prior to the orbital exploration especially because of the chemosis of the conjunctiva. The possibility of a retro-orbital pathologic condition was also considered seriously, and it was recognized that there was pressure present to produce the congestion and chemosis. However, all this time there was no exophthalmos in the right eye. He believed that this was important evidence to eliminate an intraorbital or retro-orbital growth. Although it was recognized that the second, third, fourth, ophthalmic branch of the fifth, and the sixth nerves were involved, the etiologic factor was obscure until the time of operation. For this reason and because of the infrequency of reported cases, it was felt that this case should be recorded.

TENDON TRANSPLANTS FOR PARALYSIS OF THE EXTERNAL RECTUS MUSCLE

DR. EDMUND B. SPAETH presented moving pictures of the operation of tendon transplant from the superior and inferior rectus muscles for the correction of paralytic strabismus involving the external rectus. He emphasized the advisability of employing this surgery only in those cases wherein the paralytic eye can be moved spontaneously up to the midline. In those cases in which the eye remains in paralytic convergence, this surgery can accomplish no more than an ordinary recession of the internal and resection of the paralytic external rectus. In properly selected cases 15 to 30 degrees of external rotations have been achieved following the surgery. The principles underlying the surgery are twofold. The first is a definite release in the paralytic convergence by the recession of the internal rectus and, through the use of the tendon transplant from the superior and inferior rectus muscles, cutting internal rotations ability by half. Secondly, the transplant holds the eye into eyes

front or even in the slight latent divergence, permitting the two obliques to function more adequately as external rotators. The receded internal rectus furnishes adequate convergence for near work. The surgery has its best indication where there is an acquired paralysis of the external rectus, rather than in cases of congenital palsy.

DR. LOUIS LEHRFELD said that Dr. Spaeth might recall the exhibit of two cases of the Hummelsheimer operation by him at the Wills Eye Hospital Conference several years ago. One of the patients concerned with the exhibit was seen at the Wills Hospital Clinic recently. The result was quite excellent.

There was a slight difference in the technique compared with that just shown. Instead of transplanting the sections of the tendon of the superior and inferior rectus muscles above and below the insertion of the external rectus muscle, Hummelsheimer recommends that the tendon transplants be inserted under the

insertion of the external rectus muscle.

Dr. Lehrfeld thinks that the key to success of such muscle-transplant operations rests with a firm anchoring of the transplanted tendons to their new positions. He found that this could be best accomplished by the use of silk sutures inasmuch as they are unabsorbable.

Last year he used the Hummelsheimer technique in operating on a patient who had paralysis of the superior rectus muscle associated with ptosis. To his surprise he not only obtained a fair result in restoring partly the function of the superior rectus muscle, but also obtained a reduction in the amount of ptosis.

He said that he hoped Dr. Spaeth's presentation would stimulate the surgeons present to resort to this method of tendon transplant not alone in external-rectus paralysis, but in paralysis of all the ocular muscles.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 55 East Washington Street, Chicago 2, Illinois*; Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin*. Manuscripts should be *original copies*, typed in *double space*, with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 E. Wisconsin Avenue, Milwaukee 2, Wisconsin*.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio*. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

NUTRITIONAL AMBLYOPIA (JAPONICA)

In this number and in the October, 1946, issue of the Journal are to be found reports by competent observers of cases of amblyopia in prisoners of war due to nutritional optic neuritis. These poignant papers deserve an editorial spotlight not only because they add much to our knowledge of ocular complications of avitaminosis but also because the unfortunate subjects of the afflictions were the victims of the cruel beastliness of our enemies.

There is some satisfaction in knowing that these reports will eventually be seen by present and future Jap and Hun ophthalmologists, who should never for one minute be permitted to forget that in these instances as in so many others they, the physicians of our enemy countries, violated every human feeling and law of our noble profession. We scorn and shall ever scorn them, because by their acts they have vitiated every advance in medicine for which they may have been responsible in the past, and

they have been traitors to the brotherhood of medical service to man.

American soldiers and civilians were blinded when they were helpless prisoners of war, not by shell fire, hand grenades, or bombs, but by lack of food that civilized and humane people would not withhold from a dog. They were not even given the benefit of the knowledge of the cause of their loss of sight, possessed by Jap ophthalmologists. For it was in Japan that cases of amblyopia and central scotoma due to beriberi were originally observed and reported in the world's medical literature. It makes bitter reading now.

Takaki, in 1884, in Japan was the first worker to recognize the dietetic nature of beriberi. Prior to his work this disease had been responsible for sickness in at least 25 percent of the Japanese navy's personnel. Takaki recommended replacing the rice diet in the Japanese navy by a mixed diet that included wheat bread, fresh vegetables, and milk. This resulted in the entire disappearance, by 1887, of the disease in the Japanese navy.

Professor Eijkman in Batavia in 1890 produced experimental beriberi in fowls by feeding them polished rice and cured it by giving them an alcoholic extract of rice polishings. Professor Grijns combined the work and came to the conclusion that beriberi was due to the absence of some essential ingredient from the food.

In 1907, Fletcher observed that the inmates of the Kuala Lumpur mental asylum who ate "uncured" polished rice came down with beriberi, while those who ate "cured," that is parboiled rice, escaped.

Fraser and Stanton, in 1909, performed significant, planned feeding experiments with Javanese laborers and showed that polished rice produced beriberi. Their observations were fully con-

firmed by Strong and Crowell (1912).

Caśimir Funk, working in the Lister Institute, isolated a protective substance from the rice polishings in 1911 and introduced the word "vitamine." Pure crystalline vitamin B₁ was chemically identified in 1926 by Jensen and Donath and was synthesized by Williams and his co-workers in 1936.

In 1909, H. Yamaguchi of Tokyo, Japan, reported in the *Klinische Monatsblätter für Augenheilkunde* (Volume 47, part 1, page 517) a case of retrobulbar optic neuritis due to beriberi (Kakke). The patient with general signs of the condition, chiefly edema of the extremities and polyneuritis, developed, within a few months, a central scotoma in each eye without observable fundus changes. He was treated with diuretic agents and moderate feeding, which was successful in clearing up the scotomas in a month. The author reviewed the Japanese literature and cited the experiences of Kono (1895), Komoto (1898), Tsurumaru (1899), Komoto and Aoki (1901), Yamamoto (1901), and Ichihara (1902), all of whom reported cases of loss of central vision due to beriberi. Ichihara's resume (1904) was as follows:

(a) Amblyopia and visual field changes may appear as prodromal signs two or three months before the development of the general disease.

(b) The loss of sight in beriberi occurs in badly nourished people.

(c) The amblyopia and visual-field changes in beriberi are of a temporary nature (sic).

(d) An atrophy of the temporal nerve fibers in the papilla is often found.

(e) The loss of sight in beriberi is similar to that in alcohol-tobacco-lead poisoning.

The controversy between those who believed in infection as a cause and those who believed in a toxin (in rice or fish)

as a cause is no longer an issue. Yamaguchi thought that the toxic theory (poisoning with rice, fish, and so forth) was the most acceptable. We know now, thanks to Bloom, Merz, Taylor, Roberts, Willcockson, Carroll, and others that vitamin B₁ (thiamin-chloride) deficiency is to blame.

We see, therefore, that the lack of vitamin B₁ in polished rice and its presence in quantity in the polishings of rice have been common and world-wide knowledge for many years prior to the war. Bloom, Merz, and Taylor cite an instance where in a Japanese prison camp "the rice polisher broke and unpolished rice was served for two months. A definite improvement in the condition of the men resulted during this time. On returning to the diet of polished rice, they suffered a recurrence of former symptoms."

How infinitely sad it is to consider the great and permanent evil that resulted from the criminal negligence of the Japanese medical authorities, especially ophthalmologists, in not insisting that unpolished rice, unpalatable as it may be, be given the prisoners of war. There is no evidence that any Jap physician ever ordered prisoners to be fed unpolished rice, although all could not have been ignorant of the experiments and studies that had been performed in their own country and elsewhere in the East prior to the war; or advised the commanding officer of a prison camp not to use his rice-polishing machine; or suggested that rice polishings or rice bran or Tikitiki (an extract of rice bran) be furnished the prisoners as a supplement to their terribly meager and filthy rations; or gave instructions to the prison cooks on how to parboil rice in order to spare the vitamin B₁ contained therein. This is the crime of all ophthalmologists living in Japan today.

Pioneers in the study of visual loss in

beriberi, possessed of knowledge on how to prevent this avitaminosis and how to treat it early enough to prevent permanent or irreversible changes in the optic nerve, they withheld in their hour of triumph even the lowly polishings of rice, polishings that were no doubt discarded, from their helpless and sick victims. They shall ever stand condemned.

Derrick Vail.

THE ABSTRACT DEPARTMENT

Rare indeed must be the ophthalmologist who is able to read or even to scan the whole field of ophthalmic literature in his own and other languages; to say nothing of the many excellent papers dealing directly with ophthalmology, or having some relation to it, which appear in general medical journals or in the journals of other specialties. A good abstract department undertakes to bring to the busy reader some sort of indication of the contents of the world's literature in regard to ophthalmology.

There are few ophthalmologists who read their medical magazines through from cover to cover. The longer a medical essay, the more likely it is to be skipped through, or perhaps even to be read only as to its concluding summary. The medical essay which presents no summary is particularly apt to be neglected by a large number of readers. A leading ophthalmologist of the United States once told the present writer that the first things he looked at upon arrival of the American Journal of Ophthalmology were the editorials and the Abstract Department.

Jackson's *Ophthalmic Year Book*, in its fuller development, aimed to present each year an organized survey of the world's ophthalmic literature, grouped under special headings. The Year Book was never placed upon a sound financial basis, and after many years was abandoned as

insufficiently appreciated and too expensive for continuance out of the founder's personal resources. The Abstract Department of the American Journal of Ophthalmology, approximately in its present form, was organized to offer, as far as possible, a satisfactory substitute for the Year Book.

From time to time, many criticisms of the Abstract Department have been offered. In the maintenance of the Department a number of factors must be considered. One is the ever mounting cost of publication. Some readers demand long abstracts, some short. The organization of a large corps of voluntary workers presents its own difficulties. Some busy ophthalmologists succeed in doing remarkably prompt and efficient literary work, in spite of the demands of office practice and attendance at clinics. Some abstracters show more tendency than others to drop behind in the abstract work, and must therefore be appealed to by correspondence more frequently than their colleagues. Some have less readiness in literary expression and their material therefore consumes a larger amount of the abstract editor's time and effort. Then the abstracts must be classified with care. Often the original article cannot be dealt with rigidly under one classification, and, to avoid repetition in a different section, must be given a cross reference in order best to serve the purposes of the reader who is looking up a group of papers on some special topic.

No doubt some casual readers have wondered why it was necessary to mention in the Abstract Department the titles of original papers published in the American Journal of Ophthalmology. This is to meet the convenience of authors or investigators who wish to assemble groups of references from the Abstract Department; because otherwise such an investigator or his assistant or secretary

might easily overlook the Journal's own original papers.

Now and then we hear from ophthalmologists who think that we should omit abstracts of papers dealing with rather trite or insignificant material. However, it must be remembered that to readers in small and remote communities the material furnished by these less outstanding medical reports and essays may carry valuable information and professional stimulation.

A world war brings problems in periodical medical literature as well as in other fields. During World War II the Abstract Department was deprived of access to a number of foreign eye journals. In that period we tried to make up in part for the deficiency by giving somewhat greater space to English-language publications. Now that the war is over, on the other hand, we are faced with the formidable problem created by the receipt of considerable numbers of foreign journals which appeared with more or less regularity (strange as it may seem) during the war, and editorial and publishing organizations look somewhat aghast at the heavy demands made for space by the editor of the Abstract Department. This special difficulty will naturally pass when our abstracters have had time to catch up with the accumulations.

A last, and quite important problem, is the occasional tendency of editors to feel that they cannot keep on forever but must turn over their duties to new hands. Our Abstract Department is extremely fortunate in having found, in Dr. F. Herbert Haessler, a new editor who, in spite of his regular professional engagements, is devoting himself with courage and skill to this new responsibility.

W. H. Crisp.

BOOK REVIEWS

APPLICATIONS OF GERMICIDAL, ERYTHEMAL, AND INFRARED ENERGY. By Matthew Luckiesh, D.Sc., D.E., Director, Lighting Research Laboratory, General Electric Company, Nela Park, Cleveland. New York, D. Van Nostrand Co., Inc., 250 Fourth Avenue, 1946. Clothbound, 463 pages, foreword, contents, references, index. Price \$5.50.

This delightful book deals, to quote the author, "primarily with some major effects of radiant energy and with applications that are bound to be extensive." It represents the accumulation of studies carried out over 30 years or more of association with the research laboratories of the General Electric Company, a laboratory, to quote from the writer, "with the usual personnel, but with a unique character. Its only obligation was to obtain and publish new knowledge of various aspects of light and radiant energy."

The titles of the first few chapters give a clue to the objectives and general tenure of the report: Challenging the Sun, Sunlight and Skylight, Erythema and Tan, Units and Terminology for Biological Effectiveness, and Germicidal Energy.

The author states, concerning the subject matter of the book, that, "The value of much of the published material is greatly reduced by the absence of accurate measurements and adequate identification of the spectral distribution of energy. . . . There is need for closer coordination of the knowledge of physical science with that of biology, medicine and therapy, in the various realms of education, research and practice." The author and his colleagues have made a specialty of developing measuring devices and techniques. "The results provide a major reason for writing this book."

The subject matter is approached from

the layman's point of view. Complicated formulas, both mathematical and otherwise, are studiously avoided. Yet the necessary terms and symbols are adequately explained and in logical sequence. There are rather frequent repetitions of similar ideas and principles in different chapters of the book, so that each may be read almost as a separate thesis in itself. The entire work is profusely illustrated by simple and easily comprehended graphs, tables, and plates.

The first chapter lays an excellent groundwork for what is to follow. In it, a spectroscopic analysis is made of sunlight and the means for its reproduction from artificial sources are indicated. The challenge to the sun is shown to be real indeed, in that certain beneficial spectral waves of great germicidal potency entirely absent from sunlight, such as those having a wave length of 2,537 angstrom units, can easily be produced by artificial means. It is also demonstrated how, by selection of various filtration media, undesirable wave lengths can be removed, such as those producing erythema when tanning alone is desired, or vice versa. Throughout the entire work, as previously indicated, an effort has been made to standardize the terminology and to develop yard sticks, so to speak, by which definite quantitative analyses can be established. The author feels that only by such definite terminology can scientific advance be accomplished. Much of the fourth chapter is devoted to a definition of terms, both established and suggested. Other chapters follow, dealing with the Disinfection of Controlled Air, the Infection of Communal Air, and methods for Disinfecting Air in Occupied Interiors. Emphasis is placed upon the necessity for satisfactory equipment to carry out accurate analyses of bacterial content of the air under consideration, and much detail in the description of such apparatus is

given. The treatment of water follows in succeeding chapters, with an interesting analysis of those factors which render it more or less susceptible to treatment by germicidal lamps.

Artificial sunlight and daylight for indoor illumination is considered, and its very practical application is demonstrated. The commercial aspects of such types of illumination, as shown by the fading of materials, is not overlooked; nor is the effect upon plant life and the analogy between that and the welfare of human beings neglected. The reflection and transmission of various substances is discussed and the suitability of these substances for various purposes is indicated, in the light of these findings.

One of the closing chapters enters into a rather detailed and technical description of apparatus for analyzing and measuring ultraviolet energy. The final chapter restates the thesis that, "The primary purpose of this book is to provide a scientific basis and technology for certain major uses and effects of ultraviolet energy." It proceeds to review briefly the various applications of radiant energy in the light of the scientific basis and technology expounded throughout the entire treatise.

The book is well-written in a most attractive style. It deals with subject matter of vital and rapidly growing interest to the ophthalmologist and will amply repay repeated, careful perusal, even though the author has given only passing reference to the effect of light of various wave lengths upon the eye. This omission is readily understood, as such a discussion would obviously be rather outside the scope of the present work. The makeup

of the book, print, paper, and binding leave little to be desired.

M. Hayward Post.

CIRUGIA OCULAR. By H. Arruga. Barcelona, and Buenos Aires, Salvat Editores, S. A., 1946. 845 pages, 1218 illustrations of which 119 are in color, index, bibliographies. Price unknown.

A magnificent and authoritative volume of ophthalmic surgery by one of the world's masters of the art is always a rare event of the first magnitude in our literature. This book, dedicated to his colleagues by the author and printed in Spain, leaves one spellbound over the beauty of its pages and its illustrations (the color plates are especially fine), and envious of the extent of the author's knowledge and skill in the presentation of the text. Those of us who read Spanish, even if a little, have but slight advantage over those of us who don't for the illustrations speak for themselves. The chapter on Detachment of the Retina is especially excellent as one would expect of the author, but all of the chapters are splendid and thorough and cover the entire field of ophthalmic surgery from the layout of the operating room and care of the instruments to definitive descriptions of all modern procedures including plastic surgery. The references are modern and up-to-date, and it is pleasing to note that so many are to North- and South-American authors. The author and his publishers are to be congratulated and honored by our gratitude for this outstanding addition to our surgical knowledge.

Derrick Vail.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

1

GENERAL METHODS OF DIAGNOSIS

Arruga, H. A note on the Schiötz tonometer. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1964, v. 6, Jan., pp. 85-86.

Arruga designed a scale, which is attached to the Schiötz tonometer, and which indicates the intraocular tension for each division on the Schiötz scale. This does away with the necessity of consulting the tension chart accompanying the tonometer. Each instrument must be calibrated individually. (2 illustrations.) Ray K. Daily.

Arruga, H. The annoying reflexes of the opening in the ophthalmoscope. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Aug., p. 701.

In indirect ophthalmoscopy with intense illumination one is at times annoyed by disturbing reflexes from the central hole of the ophthalmoscope. These can be eliminated by covering the edge of the hole with soot from a burning match. Ray K. Daily.

Carlevaro, Gianfranco. Proposal for a unified scheme of examination of the ocular functions. *Riv. di Oftalm.*, 1946, v. 1, pp. 28-33.

To make ophthalmologic findings comparable and reproducible, particularly for medico-legal purposes, the author proposes a specified scheme concerning the routine examination of the visual functions. K. W. Ascher.

De Ment, J. The ultra-violet ophthalmoscope. *Brit. Jour. Ophth.*, 1946, v. 30, June, pp. 370-372.

The author describes an ultra-violet reflecting ophthalmoscope of his own design and predicts a much more widespread use of this instrument. In sudden death there is a change of the normal bright green luminescence of the fundus to a dull blue and cataractous lens material emits a different hue from the surrounding tissue. Neoplasms and other diseased tissues often fluoresce differently from the normal. Morris Kaplan.

Gormaz, A. An exophthalmometer for direct measurement. *Brit. Jour. Opth.*, 1946, v. 30, June, pp. 350-353.

An exophthalmometer of transparent plastic is described. It consists of three vertical stems that slide on a horizontal millimeter scale. In use the two outer stems are adjusted so that their grooved ends can be placed on the bony orbital margin while the central stem, which also slides across a horizontal bar and ends in a small cup, rests directly on the anesthetized cornea as in a tonometer reading. The instrument is simple, inexpensive and apparently accurate. (3 illustrations.) Morris Kaplan.

Lopez, A. A. A chart for the examination of the blind spot. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Aug., pp. 698-700.

A chart similar in type to the one used on a stereocampimeter is placed in a movable holder attached to the arm of a perimeter. With the central fixation target used for fixation, the blind spot is outlined with a 3-mm. testobject on the chart. (Three illustrations.) Ray K. Daily.

Lopez, A. A. An easy and rapid method for measuring heterophoria. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Aug., pp. 697-698.

The author's device consists of a sheet of black paper, with a series of round perforations 1 cm. in diameter, separated by a distance of 29 mm. Viewed from a distance of five meters the distance between two perforations represents $\frac{1}{3}$ of a degree. By placing a vertical prism in front of the right eye, and a red glass in front of the left, two lines of perforations are seen and the extent of the lateral deviation is easily

calculated from the number of displaced perforations. Ray K. Daily.

Maione, Mario. Theoretic foundations, limits, and practical value of physiologic photometry (with criteria for correcting a photometer). *Ann. di Ottal. e Clin. Ocul.*, 1946, v. 73, Jan., pp. 33-57.

The author discusses at length the problem of photometry in its physical and physiologic aspects and indicates the conditions which should be observed for attaining the greatest possible accuracy in physiologic photometry. In his studies he employed a Maggiore photometer (now in process of production), which, being furnished with a photo-electric cell, makes for greater objectivity.

Harry K. Messenger.

Syz, Hans. The Lifwynn eye-movement camera. *Science*, 1946, v. 103, May 17, pp. 628-629.

A camera is described by means of which the sequence of eye movements and the duration of fixations may be registered. The camera uses standard 35-mm. motion picture film. The frames are changed automatically once each second, and exposure frequency of 5. to 30 per second is provided for, but this could easily be increased to 60 or more if desirable. The accuracy of the time intervals between exposures is reliable and is achieved by an electrically controlled stroboscopic device. (References.) F. H. Haessler.

2

THERAPEUTICS AND OPERATIONS

Arruga, H. Privin in ophthalmology. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Aug., pp. 673-675.

Arruga finds 0.1 percent privin supe-

rior to adrenalin, in that it produces a vasoconstriction lasting longer than that of adrenalin and without subsequent vasodilatation. He uses it in surgery as a hemostatic instead of adrenalin, and therapeutically in all types of chronic conjunctivitis without secretion and with pronounced subjective symptoms, such as allergic and chemical conjunctivitis, and the type secondary to lacrimal obstruction.

Ray K. Daily.

Barraquer Moner, J. I., and Deó Rídruejo, J. M. **Contribution to the study of penicillin therapy in ophthalmology.** Arch. med. quir. y del trabajo, 1946, Jan.

The authors report the results obtained in the treatment with penicillin in twenty-eight patients with ocular disease. They briefly describe the micro-organisms that are sensitive to penicillin. They record eight clinical histories of patients in whom penicillin was used parenterally. They believe that their results surpass those of other authors.

Jose Saenz Canales.

Brückner, R. **The effect of histamine on the eye.** Ophthalmologica, 1946, v. 111, April-May, pp. 306-309.

The severe chemosis that follows the instillation of histamine is prevented when anesthetics are used beforehand. This fact was demonstrated by the author in numerous experiments with rabbits. It also explains the negligible reaction when histamine is used as a miotic after intracapsular cataract extractions.

Alice R. Deutsch.

Campos, Evaldo. **Tuberculin therapy in ocular tuberculosis.** Rev. Brasileira de Oft., 1946, v. 5, Sept., pp. 37-42.

This is a brief statement of the author's own practice in the use of tuber-

culin. He uses relatively substantial doses. The initial dose is 0.05 or 0.1 c.c. of 1 to 1000 Koch's Old Tuberculin, intradermally; repetitions are usually given in the muscles. In the absence of general reaction the dose is doubled, and subsequent doses are usually increased each time by 0.2 c.c. of the same solution until the bulk of the solution indicates the use of 1 to 100 old tuberculin. The interval between doses is four or five days. The previous dose is repeated or the dose diminished whenever appreciable reaction occurs. A few cases are briefly cited.

W. H. Crisp.

Dunphy, E. B. **Medical progress: ophthalmology.** New England M. J., 1946, v. 235, July, pp. 117-121.

This is an excellent summary of recent advances in ophthalmology stressing therapeutic improvements. Penicillin is shown to be superior to the sulfonamides as its antibacterial action is not inhibited by autolytic processes or secretions. It has little or no effects on the regeneration of the corneal epithelium. It is not incompatible with the drugs ordinarily used in ocular infections. When penicillin is applied locally by corneal bath, a much higher concentration is found in the conjunctiva, sclera, iris, and aqueous than when given either intravenously or subconjunctivally. The application under the lid of a small cotton pack saturated with a solution of penicillin containing 20,000 units per c.c. has been shown to be very effective in producing high concentrations in the aqueous, cornea, and iris. Intramuscular and intravenous injections of penicillin probably have little effect in the vitreous chambers. Subconjunctival injections may have some effect in the anterior chamber but probably none in the vitreous.

Infections of the vitreous can probably be best treated by a single intravitreal injection of penicillin solution containing not more than 500 units. Infections of the anterior chamber require local applications by means of cotton packs. Corneal baths and subconjunctival injections are probably less effective.

Dramatic improvement has followed injections of penicillin into the anterior chamber for infections following perforating injuries. A single injection of 100 units has usually been sufficient.

A. G. Wilde.

Juler, F. and Johnson, G. T. Use of crystalline penicillin in corneal and intraocular infection. *Brit. Jour. Ophth.*, 1946, v. 30, April, pp. 204-208.

The use of crystalline penicillin massaged into the crater of a corneal ulcer is described. The pure drug was carefully rubbed into the tissue of advancing edges, massaged well into lips of cataract sections or applied to the trephine bleb in postoperative infection. Results were much better than usual and most notable was the clarity of the scars resulting from the ulcers. In one eye the drug was injected into the aqueous. Five case reports are presented. Despite many impurities in the powder, it dissolved very rapidly and there were no untoward effects.

Morris Kaplan.

Leopold, I. and Comroe, J. Effect of diisopropyl fluorophosphate ("DFP") on the normal eye. *Arch. of Ophth.*, 1946, v. 35, July, pp. 17-32.

The authors report detailed technical research of the effect of this drug on the normal eye. Diisopropyl fluorophosphate "DFP" locally instilled in the eye in low concentrations will produce prolonged miosis, ciliary spasm, false myopia, and decrease in intraocu-

lar tension. Quantitative species variations were found to exist, but the effects were most marked and prolonged in man. A 1-percent solution of "DFP" produced more prompt, pronounced, and prolonged miosis than a 5-percent solution of neostigmine bromide. "DFP" in the concentrations used has no direct effect on the iris muscle itself, since it failed to constrict the totally denervated cat iris. Its effects, therefore, are due entirely to inactivation of cholinesterase. A 0.1-percent solution of "DFP" was able to overcome the cyclopegic effect in human eyes of 4-percent homatropine hydrobromide, and a 0.2-percent solution of "DFP," that of 1-percent atropine sulfate.

No significant difference could be demonstrated between oil and water as a vehicle for "DFP" for ophthalmic use except that "DFP" is decidedly more stable in peanut oil than in water. (References.) R. W. Danielson.

Mayer, L. L. Use of penicillin ointment in external ocular conditions. *Arch. of Ophth.*, 1946, v. 35, June, pp. 688-689.

This is a preliminary report on the use of an ointment containing 1,000 units of calcium penicillin per gram combined with 1:10,000 merthiolate in 100 patients with various external ocular infections. No patient with chronic conjunctivitis was benefited. Usually infected hordeolum subsided in from three to four days without incision. In cases of chalazion the infection subsided in from four days to one week but it was usually necessary later to incise and curet the gland. Nonpurulent acute conjunctivitis failed to respond to the penicillin ointment. Acute purulent conjunctivitis was cured in from three to five days. It was noted

that superficial infections of the skin around the lids cleared dramatically with simple application of the penicillin ointment to the surface of the skin.

John C. Long.

Meyer-Hartman, W. M. The thermal treatment of rheumatic diseases with special considerations of the springs of Baden. *Ophthalmologica*, 1946, v. 111, April-May, pp. 229-241.

The anatomy, etiology, distribution and the treatment of the rheumatic diseases are discussed with special reference to Hochrein's and Huch's classification.

The effect of mineral baths on the organisms and their importance in the treatment on rheumatism are described. The springs of Baden and the routine procedures for beneficial therapy serve as an example. Alice R. Deutsch.

Minton, Joseph. Penicillin in treatment of common external eye infections. *Brit. M. J.*, 1946, no. 4470, Sept. 7, pp. 324-326.

This agent is recommended in children having the more common external infections such as blepharitis, conjunctivitis with or without corneal ulceration, and infection of the lacrimal sac.

In either adults or children an allergic dermatitis may occur following any form of local penicillin therapy and the etiology can be verified by means of the patch test. In the preparation of the ointment, water should not be used as it reduces the stability. The penicillin is not soluble in the fatty base, but when applied, the moisture of the skin or tears will slowly dissolve the penicillin, and thus prolong its action.

A. G. Wilde.

Rønne, Gerhard. Local treatment of intrabulbar infections. *Brit. Jour.*

Ophth., 1946, v. 30, July, pp. 405-419.

Rønne found that 0.2 c.c. of penicillin solution containing 100 to 500 units could be injected directly into the vitreous without great danger and with great benefit. Its effectiveness depends on the concentration of penicillin maintained in the vitreous. A bacteriocidal concentration should be maintained for at least 16 to 24 hours. Although staphylococci were used in this experiment, Rønne believes the drug is equally efficacious against all the bacteria that are sensitive to penicillin. (Bibliography.) Morris Kaplan.

Rosen, Lucien. Administration and indication of Priscol in ophthalmology. *Ophthalmologica*, 1945, v. 110, Sept.-Oct., pp. 191-205.

Priscol "Ciba" (chlorhydrate of 2-benzylimidazoline) is a vasodilator and is available in the form of eye drops, a solution to be injected, and a 10-percent ointment.

The medicament can be given whenever an active hyperemia is desired. Particularly good results were achieved in the treatment of parenchymatous keratitis, nonmyopic changes in the vitreous body, blockage of the central artery of the retina, migraine, optic neuritis, and glaucomatous atrophy of the optic nerve. Retinitis pigmentosa and certain chorioretinal conditions also were favourably affected. (References.) F. Nelson.

von Sallmann, L., Grosso, A. E., and Marsh, M. G. Ophthalmic penicillin ointments. *Arch. of Ophth.*, 1946, v. 36, Sept., pp. 284-292.

Favorable reports have been made on the treatment of certain surface infections of the border of the lid, the conjunctiva, and the cornea with penicillin ointments. It was desirable to extend

the investigations and to compare the advantages of several ointment bases and penicillin compounds.

In the present study three properties of penicillin ointments were collated experimentally: first, their irritative action on the normal rabbit and human eye; second, the stability of penicillin in various bases at room and at refrigerator temperature, and third, the penetration of penicillin from the ointment into the eye.

The authors conclude that of the nine ointment bases that were tested, two were irritating to the eye. No irritation could be attributed to any of the four penicillin compounds that were incorporated in the ophthalmic ointments. The potency of the penicillin in the salves was relatively stable in one hydrous and two anhydrous bases after twelve to sixteen weeks in the refrigerator. Storage at room temperature usually resulted in a rapid loss of potency except for two ointments prepared with an anhydrous base. No difference in the stability of the various ointments could be ascribed to the penicillin compounds in the salves. The penetration of penicillin into the aqueous of rabbits from one hydrous and two anhydrous bases was substantial. After the application of two ointments with the calcium salt, the content of penicillin in the aqueous exceeded that of salves with the sodium and ammonium salts. The resorption of penicillin was unsatisfactory from the one ointment which contained the free acid of penicillin.

R. W. Danielson.

Tomai, Evandro. The immobilization of the eyeball. *Boll. d'Ocul.*, 1945, v. 24, Jan.-March, pp. 58-60.

The author describes a blepharostat furnished with a special device by which the eyeball can be immobilized

in operations on its anterior segment. A needle with a silk suture is passed through the superior rectus tendon, the needle is removed and the two ends of the suture are clamped in the device that is attached to the upper branch of the speculum while the eyeball is gently pulled down to the desired position. (1 figure.)

Melchiorre Lombardo.

Valerio, M., and Blum, J. D. Studies on the mydriatic action of adrenaline drops. The effect of wetting agents. *Ophthalmologica*, 1946, v. 111, April-May, pp. 193-219.

The authors discuss the pharmacologic action of adrenaline solutions in general, the physiology of the adrenaline mydriasis, and its advantages compared with other mydriatics. Their own research work shows that the mydriatic effect of adrenaline drops is independent of the individual sensitivity or concentration of the drug. It is the amount of the active substance at the neuromuscular junction of the dilator of the pupil that is essential. Isotonic solutions are less irritating. Isotonicity does not greatly influence the penetration, but added wetting agents do.

Local anaesthetics favor the penetration of adrenaline chiefly because they are wetting agents. Percaïne, which is a quinine derivate, surpasses the cocaine derivatives in this respect. The adrenaline mydriasis is more pronounced in the aged and is more easily achieved. A one pro mille adrenaline solution in five pro mille percaïne gave the best mydriasis without reduction of accommodation and caused a reduction of tension, especially in the hypertensive eye. This mydriasis resists the surgical opening of the anterior chamber but is eliminated by

eserine and amineglaucon. (References.)
Alice R. Deutsch.

Wolf, A. V. and Hodge, H. C. **Effects of atropine sulfate, methylatropine nitrate (metropine) and homatropine hydrobromide on adult human eyes.** Arch. of Ophth., 1946, v. 36, Sept., pp. 293-301.

In previous reports regarding the mydriatic and cycloplegic action of these drugs the solutions used varied in strength and the doses were not given. In this report conditions have been kept constant with one drop of 1 percent solution. Under these conditions homatropine had less mydriatic and cycloplegic effect than either of the other two drugs, and recovery from its effects was the most rapid.

Methylatropine nitrate had significantly less mydriatic action than atropine. The cycloplegic action was about the same as that of atropine.

R. W. Danielson.

3

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Berens, Conrad. **Ocular fatigue.** Ophth. Ibero Amer., 1945, v. 7, no. 3, pp. 165-186.

The author describes nine clinical cases to illustrate the fact that various causes other than purely local conditions may contribute to the development of asthenopia. Persons in military service who suffer from asthenopia should be thoroughly studied in regard to questions of general medicine and neurology, as well as by a searching eye examination. The nine cases cited showed the following combinations: asthenopia associated with quadrant anopsia and paralysis of the superior oblique following an airplane accident; rapid fatigue of accommodation associ-

ated with chronic hyperplastic pansinusitis; asthenopia in an aviator associated with paresis of convergence and accommodation; asthenopia associated with convergence insufficiency secondary to sinusitis; diet as a probable cause of asthenopia associated with fatigue of accommodation and convergence; rapid effect of oxygen deficiency in a patient with subnormal accommodation and convergence; aniseikonia in a patient with anisometropia; endocrine disturbance acting through fatigue of accommodation; and tobacco affecting accommodative fatigue. In addition to measures for improving the health of the patient, orthoptic treatment seems occasionally to benefit, even in the absence of definite indications, perhaps by increasing resistance to ocular fatigue and by improving coördination and amplitude of fusion. (9 illustrations, references.)

W. H. Crisp.

Burt, Cyril. **The relation between eye color and defective color vision.** Eugenics Rev., 1946, v. 37, Jan., pp. 149-156.

The author presents the results of his studies on the relationship between the pigmentation of the iris and defects of color vision. His efforts are intended to interest others to submit further data such as pedigrees, family records and individual patients for psychologic examination. In a previous survey of school children decidedly fewer color blind were found among those who had light colored eyes. Correlation of hair color with defective color vision was negligible.

The surveys made of military men during the past showed that there were more than half again as many color defective subjects among the dark-eyed than in the light-eyed individuals. The

tests were made with Ishihara charts.

The author feels that there must be some genetic link between pigmentation of the iris and defective color vision and that the final explanation depends on further knowledge of the underlying physico-chemical processes.

Francis M. Crage.

Cristini, Giuseppe. The value of the color triangle of König and Dieterici for clinical examinations in ophthalmology. *Riv. di Oftalm.*, 1946, v. 1, Jan., pp. 15-27.

In 1936, the International Commission for Illumination accepted the König-Dieterici modification of the Young-Helmholtz color theory as a basis for measuring and standardizing colors. Haschek's microphotometer fulfills all the requirements or an exact identification of any color by a figure corresponding to that particular color and to no other. Therefore, it will be of great value for scientific as well for clinical questions concerning the color perception of normal eyes as well as of those with defective color perception. For details the original article should be studied. (References.)

K. W. Ascher.

Dekking, H. M. On adaptation. *Ophthalmologica*, 1945, v. 110, Sept.-Oct., pp. 138-169.

Investigations on the course of dark adaptation after short flashes, made by means of a quick-recording adaptometer, show that the process of adaptation is more complicated than is generally assumed. The apparatus which was designed by the author is described in detail. The study leads to a theory of retinal processes of which the well-known and much-studied adaptation curve after complete bleaching-out is a special case. A new principle is intro-

duced. It is assumed that light sensation is proportional not to the concentration of visual purple but to the difference between concentrations of visual purple inside and outside of the retinal cell. This one principle makes possible an explanation of adaptation phenomena under any experimental condition, of the origin of the after image and the peculiarities of its duration and intensity after various exposures, and of the phenomenon of simultaneous contrast. (8 diagrams, 19 curves.)

F. Nelson.

Delgado, J. M. R. Extramacular form vision. *Ophthalmologica*, 1945, v. 110, Sept.-Oct., pp. 170-190.

Extramacular perception of form was investigated by presenting eight different figures to the subject on a Ferec-Rand perimeter. The figures are a circle, a square, a triangle, a wavy line, two dots, and a narrow rectangle each of which had a surface area of 4 mm.² Two other narrow rectangles had half and twice this area. The figures were presented in each of eight meridians and the subject was required to draw what he saw at intervals of five degrees.

Pattern must be regarded as important in any test in peripheral vision. The concentrated patterns which are comparatively circular, can be more easily distinguished in a wider field of vision than straight lines of the same size which are described as dispersed pattern. A concentrated pattern of 2 to 4 mm.² surfaces can be seen in a field of vision twice as large as a dispersed pattern.

This is explained by assuming that a concentrated pattern stimulates a larger number of the visual receptors that are functionally attached to one ganglion cell and that the sum of their impulses exceeds the threshold of this

ganglion cell. The dispersed pattern stimulates a greater number of receptors but these are bound to different ganglion cells and the sum of their impulses is below the threshold of the ganglion cell.

The Bunsen-Roscoe law on the necessary constancy needed by a given mass of energy to reach the threshold of the retina must be revised. The law remains valid for stimulation of the peripheral visual cells only for cells that are associated with one derivative cell. A portion of this energy is lost if the stimulus is brought to cells in connection with several ganglia. (7 figures and charts.)

Fortin, E. P. The achromatism of the eye. *Arch. de Oft. de Buenos Aires*, 1943, v. 18, Nov., p. 598.

In this brief article the author presents his own theory to explain the achromatism of the eye.

Plinio Montalván.

Graham, R. Reduction of reflections. *Arch. of Ophth.*, 1946, v. 36, Sept., pp. 315-320.

Since 1938 Strong, whose work was done at the California Institute of

Technology, and Cartwright and Turner, whose major work was done at the Massachusetts Institute of Technology, have developed a process which combines the maximum efficiency with the greatest durability. This process, as utilized in optical lenses for the armed forces of this nation, consists in depositing a thin film of magnesium fluoride on optical surfaces in high vacuum and under considerable heat.

When light, traveling in air, impinges on the polished surface of crown glass of index 1.52, the loss is 4.2 percent at each surface. Coating with magnesium fluoride reduces this loss to 1.3 percent. In an optical system made up of many surfaces, the cumulative saving in light is considerable. In bright daylight, a reduction of ghost images due to interface reflections, and an increase in contrast and detail results. In dim illumination this conservation of light often makes an optical system useful when, before coating, it would not have transmitted enough light. The tremendous value of this process in extending, both at dusk and dawn, the period of usefulness of photographic operations, observation devices, and gunfire control systems can be appreciated.

In ophthalmic optics one finds different and more exacting conditions. At this stage of development of the science, one cannot expect a repetition of the almost-complete acceptance found in instrumental optics. For ophthalmic use the coat must be rugged indeed, for it is exposed to repeated cleaning and much abrasion. The reduction of reflections is only about 50 percent. Scratches on a coated surface are more visible. Furthermore, the gain in transmission, which is so important in a multisurface system, is practically meaningless in a two surface lens, in

which loss of light is seldom a problem.

Reflections from glasses into the eyes of the wearer occur with everyone. But it cannot be said to constitute a serious problem until the intensity of the reflections exceeds the tolerance of the patient. The tolerance of reflections will be lowest in neurasthenic and hypercritical patients.

Reflections from glasses can do more than annoy the wearer. They can, and often do, conceal the eyes of the wearer from any one looking at him. For all who wear glasses when appearing before groups of people this is a serious impediment. R. W. Danielson.

Goldman, H., and Aschmann, A. Studies on accommodation, (correction of paresis of accommodation and the physical and physiologic range of accommodation.) *Ophthalmologica*, 1946, v. 3, Feb.-March, pp. 182-186.

This study is the first attempt to measure the strength of the ciliary muscle, that is, the physiologic range of accommodation rather than the physical range. It was found that the strength of the ciliary muscle is always more extensive than the physical accommodation but it is smaller than would have been expected on the basis of the Donders-Hess modification of Helmholtz's theory. Tscherning's theory is incorrect because the physiologic range of accommodation, expressed in diopters, is always larger than the physical range of accommodation.

The authors also discuss the correction of monocular paresis of accommodation. (1 figure.) Alice R. Deutsch.

Hardy, L. H., Rand, G., and Rittler M. C. Color vision and recent developments in color vision testing. *Arch. of Ophth.*, 1946, v. 35, June, pp. 603-614.

This essay contains a condensed, simplified expression of the working hypotheses used by color vision investigators today, a note on the ICI Coordinate System and Standard Observer, comments on some typical color tests in current use, and an empiric classification of the types of color vision. It contains so much valuable material in condensed outline form that it cannot be suitably abstracted.

John C. Long.

Holmes, W. J. Night Vision. *Arch. of Ophth.*, 1946, v. 36, Sept., pp. 302-314.

In a previous article comparative data on the results of examination of night vision of 217 Caucasian and 217 Japanese students were reported. The purpose of the present paper is to furnish statistical data on the correlation that was found between the instruments used, to describe briefly some of the other instruments and technics employed in night vision testing, and to proffer a plan, based on physiologic and optical principles, for universal adoption, for the complete examination of the function of night vision.

Comparisons were made of six devices used for investigating night vision. The correlation that existed among these devices was not sufficient to warrant their use interchangeably. A partial list of additional devices used for testing dark adaptation and night vision is appended, together with objections raised against them. A thorough, systematic method of examination based on physiologic principles for the study of the function of night vision is described and its uniform acceptance advocated. R. W. Danielson.

Jasmen González, Alfonso. Frequency of refractive errors. *Arch.*

Chilenos de Oft., 1945, v. 2, Nov.-Dec., pp. 19-25.

W. H. Crisp.

Knüsel, O. New facts about contact glasses. *Ophthalmologica*, 1946, v. 111, April-May, pp. 291-294.

This paper contains a review of the history of contact lenses and the changes in their specifications. The author's own new method consists of an exact measurement of the superficial curves of the eyeball, as well as the distance from the limbus of the contact glass to the corneal center. The existence of only several fixed types in the variations of the scleral surface simplifies this procedure. Because of the lack of adequate material, the author had to use plexiglass.

Alice R. Deutsch.

Pascal, J. I. Lens efficiency—a clinical concept. *Brit. Jour. Ophth.*, 1946, v. 30, May, pp. 291-298.

The spectacle lens varies in its effectivity with its distance from the eye. It is less well known that a fully corrected emmetropic, hyperopic, and myopic eye use different amounts of accommodation for the same distance, and the magnitude of this difference in the optical instrument that consists of eye and spectacle lens may be referred to as lens efficiency. Because a corrected myopic eye uses less of its accommodation for a given distance than a hyperopic eye does the concave spectacle lens may be considered more efficient.

In the anisometropic presbyopic eye it is necessary to give a stronger addition for near work to the more hyperopic or less myopic eye. (1 table.)

Morris Kaplan.

Sloan, L. L. Selection of color vision tests for the army air forces. *Arch. of Ophth.*, 1946, v. 36, Sept., pp. 263-283.

In the previous sections it has been shown that in the selection and classification of air force personnel two types of color vision tests are needed. The basic screening test should provide a simple, rapid, and reliable means of distinguishing normal from deficient color vision. The second test, to be given only to subjects who fail the basic test, should give a reliable and valid estimate of the degree of defect.

A detailed recitation of the advantages of many types of color vision tests is given. Of the various quantitative tests investigated, the Color Threshold Test appears to be the most satisfactory for the classification of flying personnel.

A report by Wallace and associates is quoted to the effect that people with normal and deficient color vision can detect camouflaged areas with about the same ability. R. W. Danielson.

Weekers, R. and Roussel, F. Use of campimetry in dimmed light for measurement of dark adaptation of the retina. *Ophthalmologica*, 1945, v. 110, Nov.-Dec., pp. 242-258.

The state of retinal adaptation can alter the position of the isopters considerably if these are measured in reduced illumination (less than 30 Lux). A progressive increase of the visual field, taken in reduced illumination, is an excellent measure for adaptation of the rods when plotted as a function of the times of exposure to darkness.

The contraction of the field in reduced illumination constitutes a reliable and sensitive quantitative test for nightblindness.

Certain dietary deficiencies, chiefly

of proteins and lipoids, cause a concentric contraction of the field in reduced illumination. The measurement of the field of vision in reduced light is the method of choice for the discovery of scotomata of slight density; but it is important to emphasize the fact that the position of the isopters varies with the state of retinal adaptation and that nightblindness can cause a definite contraction. (2 figures, 4 adaptation curves, 3 tables, references.)

Wölfflin, E. A new apparatus for examination of stereoscopic vision. (Preliminary report.) *Ophthalmologica*, 1945, v. 110, Sept.-Oct., pp. 212-218.

The author describes a new piece of apparatus with which stereoscopic vision can be more accurately measured, since both accommodation and convergence can be completely eliminated. (1 photograph, 1 curve.)

F. Nelson..

Woods, A. C. Treatment of myopia by visual training. *Trans. Amer. Acad. Ophth. and Otolaryng.*, Nov.-Dec., 1945, pp. 37-65.

From 130 applicants 103 myopic individuals were selected and were given visual training by a group of optometrists and psychologists. Each patient was previously examined by the author and his associates. This examination included four separate visual acuity tests at 20 feet, retinoscopy, and subjective testing with a cycloplegic of 5-percent homatropine or 1-percent atropine solution. External and ophthalmoscopic examinations were made to exclude trainees with abnormal ocular tissues. Approximately three months after the visual training the patients were reexamined. Slight consist-

ent improvement on all four charts was noted in 29 percent; no consistent improvement, but an over-all improvement in both eyes in 30 percent; no change in visual acuity in 31 percent; and decreased visual acuity in 9 percent.

Results were computed in terms of the percentage of visual acuity. Although this is the only practical method, it easily creates a false impression by exaggerating slight differences of visual acuity. The improvement noted was attributed to education in the correct interpretation of blurred visual images and to beneficial psychological reactions of some patients toward their visual handicap. This study clearly shows that visual training as used on these patients was of no practical value in the treatment of myopia.

Chas. A. Bahn.

Woods, Ralph H. Some reasons for ocular discomfort. *Illinois Med. J.*, 1946, v. 89, June, pp. 276-279.

The outstanding causes of ocular discomfort in individuals wearing glasses are failure of the oculist to analyze the prescription, to balance accommodation and convergence, and to consider cyclophoria and anisometropia. Most of the discomfort occurs in desk workers, students, teachers, doctors, and lawyers. Cyclophoria is a real clinical entity and not at all uncommon. It can be measured by means of two vertical maddox rods, one red and one white. Anisometropia causes discomfort by introducing a difference in size of the retinal images and also by producing undesirable prismatic displacements. The spherical difference between two lenses should never be over one and a half diopters. Lenses should be analysed before a prescription is given to the patient. John B. Hitz.

OCULAR MOVEMENTS

Coppez, M. H. Miners' nystagmus. *Bull. Acad. roy. de med. de Belgique*, 1943, v. 8, April, pp. 212-225.

The author reviews the history of miners' nystagmus. He considers that three factors may be of etiologic importance: the darkness of the mine, toxic gases, and the elevation of the gaze. He believes that miners' nystagmus might be an exaggeration of the normal micronystagmus of fixation.

Jose Saenz Canales.

Danis, Pierre. Congenital oculo-facial paralysis. *Ophthalmologica*, 1945, v. 110, Sept.-Oct., pp. 113-137.

Congenital paralyses of the cranial nerves are rare. The author observed one infant with bilateral facial paralysis associated with bilateral paralysis of the lateral rotators of the eyes. In two others facial paralysis was unilateral. He reviews the literature extensively and presents the pertinent data in a graphic chart. On the basis of this material he presents a new classification of the congenital disturbances of ocular movement in the horizontal direction and discusses the frequency of congenital paralysis of the facial nerve within these groups. (12 photographs, 1 chart.)
F. Nelson.

Dejean, C. Measurements in strabismus operations. *Arch. d'Ophth.*, 1946, v. 6, no. 1, pp. 1-15.

Dejean has made a study of the technic of strabismus operations in an attempt to bring greater precision to the various procedures. He criticizes the classical operations because of the variability of the results obtained. He considers the operation of tendon ad-

vancement unsound since anatomic study has shown that reattachment generally takes place at the old insertion; he finds resection a more logical procedure. He considers complete tenotomy a hazardous operation and favors tendon lengthening as safer and more precise. He describes in detail his own technic of muscle surgery and stresses the importance in the resection operation of leaving a 2-mm. stump which gives complete security in the reattachment of the cut end of the tendon. A single suture is tied transversely across the tendon fibres and, in order to give greater security, the conjunctiva is included. As a substitute for tenotomy Dejean employs a tendon lengthening procedure of the same type as is used in orthopedic surgery for lengthening the tendon of Achilles. It consists in the partial sectioning of the tendon in two places on opposite sides. By varying the length of the sections a graded effect can be obtained.

The author concludes with a study of measurements and offers a table by which the effect of operations on the horizontal muscles can be estimated.

Phillips Thygeson.

Faulkner, S. H. Ocular paralysis following spinal anaesthesia. *Trans. Ophth. Soc. U. Kingdom*, 1944, v. 64, pp. 234-236.

The author reviewed the literature on the paralysis of the ocular muscles following spinal anesthesia and found that the sixth nerve was involved most frequently, the fourth and third less frequently. There was associated miosis and mydriasis.

The time of onset was usually three days to three weeks after the anesthetic in all patients. The anesthetic was followed by severe headache persisting

until the time of paralysis when diplopia became an added symptom.

Beulah Cushman.

Grignolo, Antonio. Optic neuritis and oculomotor paralyses in zoster ophthalmicus. *Boll. d'Ocul.*, 1945, v. 24, Jan.-March, pp. 60-82.

A woman, 48 years of age, had the typical lesions of herpes zoster in the territory of the first and second branch of the left trigeminus. Intense pain and high temperature accompanied the skin manifestation whereas the central vision and visual field were within normal limits in both eyes. A few days after the onset of the affection ptosis of right right upper lid and paresis of the superior rectus muscle manifested themselves together with keratitis; the right disc became pale and the vision nil. The diagnosis of acute retrobulbar optic neuritis with paralysis of eye muscles from herpes zoster ophthalmicus was made. Reëxamination a year later revealed that the paralyses had disappeared, the right disc was white and the vision nil. The etiology and pathogenesis of the optic neuritis and ocular paralysis in herpes zoster ophthalmicus is discussed at length. (Bibliography.)

Melchior Lombardo.

Just Tiscornia, B., and Lami, I. Ocular complications in tumors of the nasopharynx. *Arch. de Oft. de Buenos Aires*, 1943, v. 18, Nov., p. 557.

The authors stress the high incidence of ocular complications in tumors of the nasopharynx. They present an anatomical review in order to explain the mechanism of involvement of the eye in the evolution of these tumors. Eight cases of malignancy of the nasopharynx are reported, in five of which there was ocular involvement early in the course of the disease. Involvement of the ex-

traocular muscles is the most frequent type of complication, although ocular symptoms that result from lesions of other cranial nerves, as well as exophthalmos, may occur. Epithelioma and sarcoma are, in order of frequency, the most common tumors. Surgery and deep radium therapy is the treatment of choice when the diagnosis is made early. (Bibliography.)

Plinio Montalván.

Latorre, S., and Rios Sasiain, M. Synkinesis between the orbicularis and the internal rectus in a case of bilateral paralysis of the third nerves. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, April, pp. 351-356.

A 48-year-old woman, with lues, had a bilateral paralysis of the oculomotor nerves, with integrity of the sixth cranial nerves. With forced contraction of the orbicularis the eyes were adducted. The pupil remained dilated and the contraction of the internus could be elicited in each eye independently. The differentiation of this phenomenon, and Bell's, Piltz-Westphal's and Axenfeld-Schurenberg's disease are discussed. The author believes that this is the first case of this type of synkinesis reported.

Ray K. Daily.

Van Lint, M. A. The role of otitis in the etiology of convergent strabismus. *Bull. Soc. Belge d'Ophth.*, 1945, no. 81, April 29, pp. 31-37.

The author reviews various theories of convergent strabismus. The role of age in infection is also discussed and it is significant that spread to the neighboring areas is much easier in the younger age group. Middle ear disease in the very young can spread to the neighboring regions and may include the sixth cranial nerve. A paralysis of divergence or exaggerated convergence

may follow. Statistics are presented which reveal that 61 percent of convergent strabismus occurs in children from one to five years of age, and falls to 8 percent from five to 10 years of age and to 1 percent after 10 years of age. On the basis of these statistics, the author refuses to accept the exclusive role of hypermetropia and excessive use of convergence as the sole etiologic agent, because under these circumstances one would expect the greatest incidence of convergent strabismus to occur between the seventh and eighth years of age, after the child has learned to read. M. R. Cholst.

Mann, Ida. *Orthoptics*. The Practitioner, 1946, v. 157, August, pp. 150-151.

Mann defines orthoptics as a form of treatment designed to produce or improve binocular stereoscopic vision. She feels that the potentialities of orthoptic exercises must be thoroughly understood by the attending ophthalmologist in order to avoid disappointment after undue optimism as to their possibilities. In conclusion she states that it is obvious that orthoptic treatment combined with refraction and surgery should be considered in any case of imperfect binocular vision.

John B. Hitz.

Mayou, Sheila. *Treatment of convergence deficiency, 1933-1944*. Brit. Jour. Ophth., 1946, v. 30, June, pp. 354-370.

The method of diagnosis and treatment of convergence deficiency in the orthoptic department of the Central London Ophthalmic Hospital is presented in detail. During a three year period 1,266 patients were seen; 599 had squint, 89 had phorias, and 578 con-

vergence deficiency. After treatment 72 percent of the patients with convergence insufficiency were cured. Sixteen percent did not complete their treatment. The treatment consists of a system of voluntary convergence lessons which the patient pursues at home by pencil to nose exercises and a stimulation of physiologic diplopia. These exercises plus exercises on the synoptophore are accomplished in six half-hour lessons and apparently are all that is necessary for accomplishment of the cure. Morris Kaplan.

Simonelli, Mario. *A case of Parinaud's Syndrome*. Riv. di Oftalm., 1946, v. 1, Feb., pp. 110-123.

A woman, 36 years of age, became ill one year before admission to the Firenze Eye Clinic where a paresis of convergence, a paralysis of the depressors, a paresis of the left trochlear nerve, and anisocoria accompanied by Argyll-Robertson pupil, were found. The acute illness is assumed to have been an attack of epidemic encephalitis that involved the mesencephalon. Problems of localization, particularly of the Argyll-Robertson sign, are discussed. (References.) K. W. Ascher.

Smith, James W. *Medical significance of ocular torticollis*. Bull. Hosp. for Joint Diseases, 1945, v. 2, Oct., pp. 99-109.

Smith indicates the varying etiology and points out how valuable routine photography may be. Photographs are made of the patient, stripped to the waist, as he stands in front of a black screen on which thick vertical and horizontal white lines are ruled to form $2\frac{3}{4}$ -inch squares. The screen is seven feet high and three feet wide. (References.) F. H. Haessler.

CONJUNCTIVA

Badir, Camil. **Schistosomiasis of the conjunctiva.** Brit. Jour. Ophth., 1946, v. 30, April, pp. 215-221.

Schistosomiasis of the conjunctiva is very rare in relation to the large number of patients affected with bilharzia in Egypt.

The pathologic report on a tumor removed from the conjunctiva of an Egyptian boy is presented. The mass resulted from schistosomiasis. Numerous ova were easily seen and for the first time the adult male and female *Bilharzia* worms were seen in situ in the conjunctival tissue. The life cycle of the worm is described and several possibilities for the route between the right heart and the conjunctiva are suggested. None of these completely satisfied the author. (3 illustrations.)

Morris Kaplan.

Bouquin, J. B. **Parinaud's conjunctivitis and the syndrome of Löffler.** Ophthalmologica, 1946, v. 3, Feb.-March, pp. 73-95.

The author discusses in detail the differential diagnosis and the possible etiology of Parinaud's conjunctivitis and also suggests a possible allergic origin. He observed a boy, eight years of age, who had various intestinal parasites, Parinaud's conjunctivitis and Löffler's syndrome. The latter consists of mild transient pulmonary infiltration, lymphocytosis, slight increase in sedimentation rate, and a characteristic rise in an eosinophilia which typically follows the height of the pulmonary infiltration. It is an allergic reaction. (References.)

Alice R. Deutsch.

Colombo, Gian Luigi. **Conjunctival reaction simulating a tumor.** Boll.

d'Ocul., 1945, v. 24, Jan.-March, pp. 52-57.

A girl, 9 years of age, had a reddish fleshy formation that protruded from the lid aperture at the inner angle of her left eye. It originated from the upper fornix and measured 3 cm. in length, 1½ cm. in width and 5 mm. in thickness. It was removed at its base. Microscopic examination revealed a mass that consisted of blood vessels of different sizes and of enlarged lymphatic vessels and covered by epithelium. Embedded in the mass was a piece of twig from a broom which had been introduced in the conjunctival sac for fun.

Melchior Lombardo.

Goldfarb, A. A. and Seltzer, I. **Primary tuberculosis of the conjunctiva.** Am. J. Dis. Child., 1946, v. 72, Aug., pp. 211-215.

Primary tuberculosis of the conjunctiva is rare, unilateral, usually occurs before the age of thirty years, and is characterized by involvement of the satellite and preauricular nodes. A boy, ten years of age, developed swelling of his right preauricular node and also of a node under the jaw. Two days later swelling of the right eye was noted and a well defined dirty ulcer was present in the conjunctiva. Biopsy revealed typical tubercles with acid-fast bacilli, and scrapings cultured on Petragrani medium produced a growth of acid-fast bacilli. (2 figures.)

I. E. Gaynon.

Knüsel, O. **Double staining with scarlet red and methylene blue. The clinical evaluation of a twin dye of the conjunctiva in vivo.** Ophthalmologica, 1946, v. 111, April-May, pp. 295-297.

The normal conjunctiva does not stain with either scarlet red or methylene blue, except for isolated epithelial

cells and droplets in the secretion or the tears. Whenever such staining appeared in the grossly unchanged conjunctiva some infiltration was found at biopsy. The stained corneal cells appear brown in reflected light and dark red in transillumination. The conjunctival cells are brown or wine red.

This test might be a diagnostic aid in patients with apparently mild conjunctival irritations and exaggerated discomfort. Alice R. Deutsch.

Marks, E. O. Treatment of trachoma. *Brit. Jour. Ophth.*, 1946, v. 30, April, pp. 213-215.

The author presents a plea for milder local therapy of trachoma. He agrees that sulfonamides affect the secondary infection but have little effect on the disease itself. In his less virulent cases he simply uses boric acid lavages and instillations of zinc sulphate solution. His results have been very satisfactory.

Morris Kaplan.

Mosquera, Sanchez. Operation for recurrent pterygium. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Oct., pp. 856-858.

The author excises the pterygium, and covers the defect with 3 by 8-mm. sliding flaps of healthy conjunctiva taken above and below the pterygium. Recurrences were especially frequent when the defect was carefully covered up to the limbus. When the raw area close to the limbus was left uncovered the fibrous cicatricial tissue, firmly adherent to the sclera, acted as a barrier to the recurrence of the pterygium.

Ray K. Daily.

Rados, A. Reticulum cell sarcoma of the conjunctiva. *Arch. of Ophth.*, 1946, v. 35, April, pp. 400-414.

Tumors of the hematopoietic system

are discussed in considerable detail. Reticulum cell sarcoma is regarded as a form of lymphosarcoma which may arise in lymph nodes but may also originate in various organs, including bone. Metastasis is by the lymphatics. The ophthalmic literature contains two cases diagnosed as reticulum cell sarcoma. In both of these cases the process was local, without the systemic involvement characteristic of reticulum cell sarcoma. The author reports the case of a 29-year-old man with marked papillary hypertrophies of the conjunctiva of the left eye and preauricular adenopathy. A biopsy of the conjunctival mass was characteristic of reticulum cell sarcoma. Roentgen therapy was instituted. About five months later the patient experienced unbearable pain in the back, had a septic temperature and died about seven months after the tumor appeared on the conjunctiva, with symptoms suggestive of multiple metastases in the spine. (References, 2 illustrations.)

Robertson, E. C., and Morgan, A. L., Effect of added vitamin A on conjunctivitis and level of vitamin A in blood. *J. Nutrition*, 1946, v. 31, April 10, pp. 471-484.

The experiment reported in this paper was performed in an attempt to verify a report by H. D. Kruse (1941) that 99 percent of a group of adults in low income brackets had diminished transparency of the bulbar conjunctiva, due to avitaminosis A.

In this experiment, half of a group of 40 student nurses (on normal diets) were given 50,000 units of supplemental vitamin A daily; the other half were observed as controls.

The authors used an arbitrary classification for conjunctival transparency,

based on the clearness with which episcleral vessels could be seen in slitlamp examinations. They were unable to note any significant changes in the degree of conjunctival "transparency" after two years of added vitamin A, nor were there any differences between the experimental and the control groups. Blood levels of vitamin A were not significantly different in these two groups after two years of therapy (recorded 11 to 13 hours after ingestion of vitamin A.) It was concluded that the conjunctival thickening, which was reported to be present, to some degree, in every subject, was not due to avitaminosis A. Benjamin Milder.

Sayrum, Adnan. An ocular complication of exudative erythema multiforme. *Göz Klinigi*, 1946, v. 4, no. 1, pp. 1-4.

The author describes an erythematous patch that occurred on the conjunctiva in a man 25 years of age, in the course of erythema multiform that involved the upper portion of his trunk. F. H. Haessler.

Shimkin, N. I. Conjunctival hemorrhage due to infection of Newcastle virus of fowls in man. *Brit. Jour. Ophth.*, 1946, v. 30, May, pp. 260-264.

A case of hemorrhagic conjunctivitis due to the Newcastle virus in a human is reported. This virus is the cause of a fatal hemorrhagic disease of fowls and has very rarely occurred in man. When it does occur, infection is by direct contact and pursues a very benign course that is complete in 7-14 days. Morris Kaplan.

CORNEA AND SCLERA

Almeida, Antonio. Kerataconus and persistent thymus. *Bol. da Soc. de Med.*

e Cirurg. de Campinas, 1946, v. May, pp. 113-117.

In patients from eight to 39 years of age the author was able to demonstrate hypertrophy of the thymus, immediately after anterior pneumomediastinum had been produced by the technique of Cordarely, by means of radiographic studies according to the method of Alamilla.

He believes that irradiation of the thymus may not only reduce the size of the gland but also retard the development of the corneal condition with remarkable increase of the visual acuity. Jose Saenz Canales.

Amsler, Marc. Classic keratoconus and incomplete keratoconus. Arguments concerning a common etiology. *Ophthalmologica*, 1946, v. 3, Feb.-March, pp. 96-101.

Four facts support the author's theory of a common origin of classic and incomplete keratoconus:

- (1) the condition of the second eye.
- (2) the morphologic evolution of the corneal deformity, from a mild irregular astigmatism through all the stages of progressive thinning and conus formation of the severe classical form.
- (3) the occurrence of classic keratoconus in some members of a family and an incomplete mild keratoconus in others and (4) the development of a classic keratoconus from an incomplete one in the same person. (7 figures.)

Alice R. Deutsch.

Arruga, H. A new technic for corneal tattooing. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, June, pp. 423-426.

Arruga uses ordinary China ink. He injects it with a tuberculin syringe and a fine needle into the layers of the corneal parenchyma. He outlines the pupil with a superficial trephine, which

cuts $\frac{1}{2}$ to 1 mm. deep. The groove thus formed limits the penetration of the ink. The advantage claimed for the procedure is the ease of execution, and the stability of the postoperative result.

Babel, J., and Campos, R. **The regeneration of nerves in corneal grafts.** *Ophthalmologica*, 1946, v. 3, Feb.-March, pp. 140-145.

Four corneal grafts removed in a second or third keratoplasty were studied by means of a modified Bielschowsky stain. The nerves in a graft develop in relation to the vessels for several weeks. Their regeneration is slow but eventually they become more numerous than in the normal cornea. The distribution differs from a normal cornea and the subepithelial net is always absent. This might account for the hyposensitivity of the corneal transplant. An early regeneration of the nerves may be important for the metabolism of the graft and its eventual transparency. (7 figures, references.)

Alice R. Deutsch.

Bellows, J. G. **Influence of local antiseptics on regeneration of corneal epithelium of rabbits.** *Arch. Ophth.*, 1946, v. 35, July, pp. 70-81.

During World War II the incidence of ocular injuries was unusually high. Recent reports have pointed out that a wide variety of agents affect adversely the healing of the epithelial defects of the cornea. No agent has yet been discovered which increases the rate of healing.

Bellows reviews the literature regarding the now well-known retardation of healing due to the use of local anesthetics. The effect of antibacterial agents commonly used in ocular therapeutics on the regeneration of the

corneal epithelium, has not been reported.

Young adult rabbits, weighing approximately 2 Kg., were employed in this investigation. The cornea was anesthetized with a 4-percent solution of cocaine hydrochloride, chosen not only for its anesthetic qualities but for its drying effect, which facilitated the removal of the epithelium; this was accomplished by rubbing the cornea with dry gauze; to make certain that the entire cornea was denuded of its epithelium, the eyes were stained with fluorescein. The course of regeneration was observed by daily examination, facilitated by fluorescein staining.

The drugs to be investigated were instilled in the left eyes of rabbits three times daily, and a similar amount of isotonic solution of sodium chloride in the right, or control eye. Five rabbits was the minimum number used for each drug. Aqueous solutions of the following substances were investigated: mild silver protein (10 percent), zinc sulfate (0.5 percent), merbromin (2 percent), phemerol chloride (1:2,500 concentration in 2-percent boric acid solution), mercuric oxycyanide (1:5,000), metaphen (1:2,500), merthiolate (1:2,500), acriflavine (1:1,000), zephiran chloride (1:3,000), penicillin (1 c.c. containing 2,500 Oxford units) and sodium sulfathiazole (2 percent).

The untreated eyes healed more rapidly than the treated eyes in nearly all cases. Phemerol chloride solution delayed the healing only slightly and produced no permanent alterations in the cornea. Sodium sulfathiazole, in 2 percent aqueous solution, and penicillin, in a concentration in which 1 c.c. contained 2,500 Oxford units, neither delayed the regeneration of the epithelial covering nor produced corneal opacities.

Repeated instillations of the common local antiseptics are not recommended in the treatment of corneal injuries. When the possibility of infection is great, the aqueous solution of sodium sulfathiazole or penicillin may be used. (References, 10 illustrations.)

R. W. Danielson.

Bischler, V. The nodular corneal dystrophy of Salzmann. *Ophthalmologica*, 1946, v. 3, Feb.-March, pp. 111-119.

Salzman's nodular dystrophy represents a clinical, pathologic, and etiologic entity and may be well distinguished from Groenouw's nodular dystrophy, a variation of which it was originally thought to be.

Prominent, round, well outlined nodules of considerable size and bluish white color, located in the anterior third of the corneal parenchyma and a shiny epithelium characterize the clinical appearance. The pathologic picture is characterized by a thinned epithelium with flattened cells and no basal layers, destruction of Bowman's membrane, and a stroma that is poor in fixed cells and has pale, swollen fibers, hyaline masses, and no vascularization.

The author describes two observations of his own. After conservative treatment had failed corneal transplants gave excellent results. (3 figures, references.)

Alice R. Deutsch.

Bürki, E. Hereditary epithelial dystrophy (type Meesmann). Another pedigree. *Ophthalmologica*, 1946, v. 3, Feb.-March, pp. 134-139.

The existence of hereditary corneal dystrophies which fit neither into Buckler's nor Franceschetti's and Babel's classification makes a rearrangement of these groups necessary. This was done by the author. He also de-

scribes a familial corneal degeneration restricted to the epithelium, which affected Bowman's membrane only slightly. Meesmann published a similar case. (3 figures.)

Alice R. Deutsch.

Campbell, Dorothy. A note on the treatment of hypopyon ulcer. *Trans. Ophth. Soc. U. Kingdom*, 1944, v. 64, pp. 256-259.

The author reports the results obtained in treating hypopyon ulcer with sulfonamides. She compares the results with a group in which the sulfonamides were not used. The sulfonamides were administered in full doses for at least 48 hours and the average length of stay in the hospital was 28 days.

The early use of a sulfa drug after a foreign body injury of the cornea was a satisfactory preventive. Sulfa drugs administered locally and by mouth combined with mild cautery and the injection of foreign protein produced the most satisfactory results.

Beulah Cushman.

Castan, J. H. True microcornea with myopia. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Aug., pp. 693-696.

A patient is described who had myopia of eleven diopters with myopic fundus changes, and whose right eye had a microcornea and a large coloboma of the choroid and optic nerve. The diameter of the right cornea was 8 mm., and that of the left 10. The radius of the corneal curvature was 6.9 mm. for the right, and 7.4 for the left. The phenomenon is rare. The differential diagnosis between microcornea and cornea plana is explained in detail. The hereditary transmission of the affection appears to be recessive, and not sex-linked.

Cogan, D. G., and Kinsey, V. E. **Action spectrum of keratitis produced by ultraviolet radiation.** *Arch. of Ophth.*, 1946, v. 35, June, pp. 670-677.

The action spectrum for keratitis produced by radiation was determined on rabbit eyes, with the radiant energy produced by a large quartz monochromator. Changes in the cornea were studied by means of the biomicroscope and slitlamp. The cornea was found to have a peak sensitivity to ultraviolet radiations at wavelengths of about 288 millimicrons, with a sharp decline in sensitivity to either side of the peak. The amount of energy necessary to elicit an ocular reaction at 288 millimicrons was approximately 0.15×10^6 ergs per square centimeter. Although the absorption peak of the corneal epithelium corresponded to that of nuclear protein (265 millimicrons), the peak of the action spectrum corresponded more nearly to the absorption peak of albumin and globulin (280 millimicrons). From this it may be inferred that the photochemical reaction in the cornea is due to a selective absorption by a substance having a peak in the wave-lengths longer than that of nucleoprotein or by certain constituents only of the nucleoprotein molecule. The transmission characteristics of various types of common glass were measured for that portion of the spectrum which is responsible for keratitis. (References, 5 illustrations.) John C. Long.

Corrado, M. **Corneal complications in malariotherapy.** *Ann. di Ottal. e Clin. Ocul.*, 1946, v. 73, Jan., pp. 22-32.

Corrado reports two cases of herpetic keratitis (one of simple herpetic keratitis and the other of dendritic keratitis) occurring shortly after the final attack of fever induced by inoculation with malaria for treatment of

neurosyphilis. He deems the malarial parasite and the fever to be merely agents that precipitate but do not cause the keratitis. The presence of the herpes virus is of course necessary, but general and local factors are likewise important. A general predisposing cause is weakness of the organism as a whole, either existing before the induced malaria or resulting from the action of the malarial toxin. A noteworthy local cause is, in his opinion, a lability of the corneal nerves, which may be ascribed to the antecedent luetic infection or to a vitamin B₁ deficiency.

He suggests that ocular complications in malariotherapy can possibly be prevented by the concomitant administration of vitamin B₁ because of its regenerative action on the nerve fibers, and of vitamin A because of its protective and regulatory action on epithelial regeneration.

Harry K. Messenger.

Diaz-Caneja, E. **Blue scleras and imperfect osteogenesis for Lobstein-Vrolick's disease.** *Arch. de la Soc. Of. Hisp.-Amer.*, 1945, v. 5, Aug., pp. 630-655.

An exhaustive review of the literature, and a report of two genealogical trees with tabulated data of the symptoms in 11 cases are presented. The inheritance of the disease is dominant, without sexual predilection, and is attributed to a hypoplasia or a dysplasia of the mesenchyme, with consequent disturbance in the development of the mesoderm and in the calcium metabolism. Blue scleras were found in 94.4 percent of the reported cases, fractures in 55.9 percent, and otosclerosis in 23.7 percent. Blue scleras are thus the most frequent symptom of the disease. Opinions differ as to the cause of

the blue color. Most investigators attribute it to a thinning and consequent increase in the transparency of the sclera. Vogt disagrees with this view, and concluded from biomicroscopic studies that the sclera is not thinned, and that the blue color is due to a hyalinization of the fibrous tissue. In the eleven cases seen by the author there was complete absence of the normal biomicroscopic structure of the vitreous in seven patients. It had a gelatinous appearance without a fibrillary component. The author believes that this condition is not a disorganization secondary to an inflammatory process, but a true primary aplasia of the vitreous which is due to a dysfunction of the mesenchyme. The arcus lipoides, found in three of the eleven patients is also attributed to the mesenchymal dysfunction. (3 illustrations, 4 tables.)

Favaloro, G. Introduction to the study of the physiology and primary pathology of the lamino-endothelial layer of the anterior chamber of the human eye. *Boll. d'Ocul.*, 1944, v. 23, Oct.-Dec., pp. 229-242.

Synthesizing all physiologic, experi-

mental, and pathologic phenomena that he had evaluated in his dissertation, the writer states that although the cornea is formed by three layers of different embryologic origin these strata are so intimately related structurally and functionally as to be interdependent in their pathologic reactions. The parenchyma situated between the two principal protective layers establishes the means of the relationship. The primary pathologic changes of the Descemet endothelial layer became manifest as dystrophic, degenerative, and inflammatory lesions. These lesions, an "endotheliosis" and an "endothelitis," should be emphasized as the subject of a new chapter in ocular pathology. (Bibliography.)

Franceschetti, A., Sarasin, R., and Balovoine, C. Bucky's rays or Grenz-rays in ophthalmology. *Ophthalmologica*, 1946, v. 111, April-May, pp. 302-306.

Bucky's rays occur in the spectrum between the X rays and the ultra-violet rays. Their outstanding physical characteristic is their absorbability. This explains their value in skin diseases and superficial corneal lesions. The application to the cornea is direct for three or four minutes and the adjoining tissues are protected by paper only. The dosage recommended varies from 70R (Monjukowa) to 150R (Krasso). Three to four treatments are enough.

Bucky's rays are recommended for intractable corneal inflammations such as disciform keratitis, herpes zoster, ophthalmicus, and recurrent corneal ulcers. (References.)

Halbertsma, K. T. A. *Staphyloma sclerae verum peripapillare congenitum.* *Ophthalmologica*, 1945, v. 110, Sept.-Oct., pp. 206-211.

The author describes congenital peripapillary staphyloma that he chanced to see in a girl, six years of age. She had bilateral myopia (3 D.) and the visual acuity was markedly reduced in both eyes. The field of vision was normal, except for an irregular blind spot. The tension and motility were normal in both eyes. The differential diagnosis is discussed in view of the congenital abnormalities of the disc; the anomaly is rare as there are only 10 cases to be found in the literature. (1 figure, references.) F. Nelson.

Jaume, G. C. *Blue sclera and parenchymatous keratitis.* *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, March, pp. 238-244.

Parenchymatous keratitis is reported in a woman, 21 years of age, with positive luetic serologic reactions. Seven members of three generations in her family had parenchymatous keratitis, blue scleras, recurrent fractures, and deafness. The history of the pathogenesis of these inherited conditions is briefly reviewed. Ray K. Daily.

Katzin, H. M. *Aqueous fibrin fixation of corneal transplants in the rabbit.* *Arch. of Ophth.*, 1946, v. 35, April, pp. 415-420.

Corneal grafts were performed in rabbits, using fibrin formed in the anterior chamber as the only fixing agent. The formation of fibrin was first inhibited by the intravenous injection of heparin. When fibrin formation was desired, thrombin that contained globulin was introduced into the anterior chamber and on the surface of the graft. This resulted in the prompt formation of a dense layer of fibrin. The technique used is described. The grafts held in 86 percent of 37 eyes and remained clear in 48 percent. (2 illustrations.)

Lowenstein, A. A contribution to the pathology of Bowman's membrane. *Brit. Jour. Ophth.*, 1946, v. 30, June, pp. 317-323.

Of the tissues of the cornea Bowman's membrane has the slowest metabolism. In those conditions inhibiting metabolism of the cornea, such as glaucoma, hypertensive retinopathy and various injuries, this membrane suffers first and most. Calcification and various types of degeneration of Bowman's result. A histological study of these changes is presented. (12 illustrations.)

Morris Kaplan.

Matteucci, P. Corneal lesions in Hodgkin's Disease. *Riv. di Oftalm.*, 1946, v. 1, Feb., pp. 85-93.

The lacrimal glands, the lids, orbital tissues, conjunctiva, and, rarely, the cornea may be affected in Hodgkin's disease. Fundus lesions are more common. The scarcity of reticulo-endothelial elements in the ocular tissues may explain the rare occurrence of ocular complications, although Gasteiger and Ciotola found cellular elements in the cornea that resemble reticulo-histiocytes. A woman 27 years of age, who had been under treatment for a typical Hodgkin-Sternberg disease for four years, developed photophobia and lacrimation and a bilateral marginal keratitis with definite hypesthesia. Etiologic investigations, including inoculation into a rabbit's cornea, failed. The keratitis did not respond to the usual local treatment. X-ray treatment, applied to the glandular masses of the patient's neck, was followed by improvement of the corneal lesions. Simi-

lar experiences have been reported by Sachs (1928), Lagrange (1932), and Morax (1932). The corneal ulcers sometimes resembled herpetic keratitis. (1 colored plate, references.)

K. W. Ascher.

McArevey, J. B. A statistical inquiry into the incidence of phlyctenular disease in Dublin. *Trans. Ophth. Soc. U. Kingdom*, 1944, v. 64, pp. 279-299.

The author selected three periods for comparing the incidence of the disease: the war period 1915-18, a normal period, 1936-38, and the present war, 1939-41. The trend of the disease increased during both war periods and was greatest in the areas of poor housing associated with poverty.

The sex and age distribution was alike in all periods. The disease occurred predominantly in females. Infants of both sexes one to four years of age showed an increased incidence during the period 1939-41 as compared to the 1915-18 period.

There was a gradually rising incidence from March to July, decreasing from September to December.

The type of the disease over the whole ten year period showed 25 percent of the corneal type, 22 percent limbal and 19 percent conjunctival phlycten. The phlyctenular keratitis was the usual disease of the infant, limbal of the young adult and the conjunctival phlycten, the least common, was associated with the better nourished child or young adult with active tuberculosis. Eighty-five percent of the patients had one attack in the period 1936-41 and 27 percent had attacks that persisted 40 days or more. Beulah Cushman.

O'Donovan, W. J., and Michaelson, I. C. Epidemic keratoconjunctivitis as-

sociated with skin lesions. *Brit. Jour. Ophth.*, 1946, v. 30, April, pp. 193-204.

The authors compare 33 cases of epidemic keratoconjunctivitis with 33 cases of concurrently seen keratoconjunctivitis associated with skin lesions, especially seborrhea of scalp and face. It was decided that the two eye conditions were identical although those in the latter series were more severe and more prone to complications. An analogy is suggested between the skin lesions associated with keratoconjunctivitis and those associated with herpes of the cornea. (3 diagrams, 8 illustrations.)
Morris Kaplan.

Palomar, A. P. Sato's posterior partial keratoplasty in the treatment of keratoconus. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, June, pp. 427-433.

The keratotomy is made with a short discission knife, which is introduced at the limbus, and passed across the anterior chamber to the opposite pupillary border. The handle of the knife is then depressed, the blade cutting horizontally across the cornea, through the endothelium, Descemet's membrane, and part of the corneal parenchyma. A compressive bandage is worn for two months. Sato claims that the cicatrization flattens the corneal cone. The author's first patient, examined nine months after the operation, was found to have the keratoconus flattened, and vision was improved from 1/14 in the right eye, and 1/22 in the left, to 3/10 in each eye. In the second patient with keratoconus in the left eye, examinations six and nine months after the operation revealed a flattening of the corneal cone, and a visual acuity improved from 1/15 to 1/4.

Rea, R. L. Arsenic keratoconjunctivitis. *Trans. Ophth. Soc. U. Kingdom*, 1944, v. 64, pp. 222-223.

A patient took nine vaginal suppositories by mouth by mistake over a period of four days. Acute arsenical poisoning appeared after four days with an acute dermatitis and keratoconjunctivitis evidently due to sensitivity to arsenic. It responded to treatment with benzedrine.
Beulah Cushman.

Reese, Maj. F. M. Edema of corneal epithelium caused by atabrine. *Bull. Johns Hopkins Hosp.*, 1946, v. 78, June, p. 325.

The author reports case histories of three patients who had similar corneal epithelial changes attributable to atabrine. In each case, there was epithelial edema, causing reduced visual acuity, with no pericorneal injection, no fluorescein staining, and no associated symptoms other than the blurred vision.

All three patients had been receiving atabrine in dosages in excess of 0.1 gram per day (the "suppressive dose"). All three recovered completely when the atabrine was withdrawn, and in each instance a severe recurrence of the corneal edema was precipitated within three to six days by renewed use of the drug. Complete recovery took place in 20 to 25 days after completely withdrawing the atabrine. There were no residual corneal changes.

Benjamin Milder.

Rintelen, F. Etiology and therapy of the so-called keratoconjunctivitis epidemica. *Ophthalmologica*, 1946, v. 3, Feb.-March, pp. 108-111.

The clinical diagnosis of epidemic keratoconjunctivitis can be made only with the slitlamp. The epidemiology, etiology, and the mode of transmission

are unknown. A virus that is related to the herpes virus may be the cause, therefor the author recommends abrasion of the corneal epithelium and cauterization with iodine. This treatment was successful in three patients.

Alice R. Deutsch.

Rintelen, F. **Penicillin therapy of sirpiginous ulcer.** *Ophthalmologica*, 1946, v. 3, Feb.-March, pp. 102-107.

The author stresses the importance of smears in sirpiginous ulcer of the cornea as a guide in chemotherapy. He reports a case of severest sirpiginous ulcer. *Staphylococcus aureus* was found and the eye improved remarkably under local penicillin therapy only.

Alice R. Deutsch.

Robles, E. R. **New observations on keratitis caused by alcohol fumes.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, April, pp. 257-261.

The author describes an acute keratitis with severe irritative symptoms, without secretion, caused by fumes of alcohol from a shampoo. The shampoo was used the evening before the onset of the ocular symptoms. The objective lesion consists of a circular or oval, central or slightly decentered corneal erosion. Robles believes that the alcohol fumes dry the corneal epithelium, which exfoliates the next day, and produces the clinical picture described.

Ray K. Daily.

Sellas, J. and Casanovas, J. **Herpetic keratitis as an industrial accident.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, April, pp. 262-272.

A review of the literature on the role of trauma in the etiology of herpetic keratitis, and the problem of compensation is presented. Reference is made to the work of Gruter, Schieck, and Amman. The authors take a careful

history of each injury, examine the patient on the day of the injury, and keep a carefully charted record of the extent and progress of the traumatic lesion. Herpetic lesions that appear earlier than the second day after the injury are regarded as pre-existent to the injury. Herpes that develops after the second day and within six months after injury is regarded traumatic. A recurrence of a keratitis following an injury in a patient with a history of herpetic keratitis is also regarded traumatic.

Sorsby, A., and Symons, H. M. **Amniotic membrane grafts in caustic burns of the eye.** *Brit. Jour. Opth.*, 1946, v. 30, June, pp. 337-345.

Extraordinary results were obtained in 30 cases of second degree caustic burns of the eye, 22 of which were due to lime. The eyes were first treated with penicillin and a graft was applied, preferably on the day of the accident. The graft consisted of dried, fat-free amniotic membrane folded over on itself several times. It was made to cover the entire burned area and was held in place with black silk sutures. Both eyes were bandaged for 48 hours. At the end of that time the graft was transparent and invisible. The burnt corneas did not stain and the conjunctivas were white. Sutures were removed on the third or fourth day and the eyes left open. Complications and sequelae were almost nonexistent and the vision was most satisfactory. The authors suggest that more was involved than a simple mechanical protection; perhaps some specific biologic, therapeutic action occurs. (References.)

Morris Kaplan.

Streiff, E. B. and Zwahlen, P. **Band-shaped corneal degeneration in one**

family. *Ophthalmologica*, 1946, v. 3, Feb.-March, pp. 129-134.

There are three forms of bandshaped corneal degeneration. The traumatic form is caused by a prolonged and constant chemical irritation. The secondary variety, follows severe intraocular diseases such as uveitis or glaucoma. The primary form appears in a senile and infantile variation, is very rare, and belongs to the familial corneal degenerations.

The authors report the clinical history and findings in three eyes of the third group and a pathological description of one of the corneas in which a perforating keratoplasty was performed. (2 figures, references.)

Sykes, E. M. Fungus infection of the cornea; a case report of keratomycosis due to monilia. *Texas St. J. Med.*, 1946, v. 42, Sept., pp. 330-332.

Three days after a foreign body had been projected against his eye this patient developed a linear dendritic type of ulcer in the center of the cornea. There was marked congestion, the ulcer was shallow and undermined, and the floor seemed covered with a thin gray adherent membrane. The aqueous was relucant. Scrapings from the ulcer revealed *Monilia albicans*, which grow on Sabouraud's medium. A saturated solution of potassium iodide (90 drops daily) was prescribed and all inflammatory symptoms disappeared in two weeks. A short review of the literature is given. (2 figures.)

I. E. Gaynon.

Thomas, C. I. Preservation of corneal tissue for transplation, *Arch. of Ophth.*, 1946, v. 36, Sept., pp. 321-327.

With the advent of the corneal transplantation operation, there has been a

gradual intensification of interest in the donor material to be used for this operation. The institution of the Eye Bank for Sight Restoration to supply adequate material for this operation is a step forward, for this organization facilitates a rapid distribution of donor material to the proper place. However, there are widespread misconceptions.

A series of eyes was studied to determine the efficacy of various mediums that might be useful in the preservation of corneal tissue. Isotonic solution of sodium chloride, Hartmann's solution, Hartmann's solution and 5-percent dextrose, plasma, oxygenated plasma, and freezing agents, such as liquid nitrogen and sodium pentothane (isopenthane) were used.

Corneal tissue will remain clear and of normal thickness and can be used suitably for transplantation for as long as three days. After three days there may be areas of transplanted cornea that tend to retain transparency, but tissue kept for one week becomes uniformly opaque. For keeping corneal tissue clear, a solution may be used that is as nearly isotonic with the body fluids as possible, for example, saline solution, Hartmann's solution, or blood plasma.

Corneal tissue to be used for transplantation should be obtained from a fresh specimen and used within a relatively short period in order to obtain the best surgical results.

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Amsler, M., and Huber, A. Methods and first clinical results of studies of the blood-aqueous barrier. *Ophthal-*

mologica, 1946, v. 3, Feb.-March, pp. 155-176.

The authors describe a new method for examining the blood-aqueous barrier. They inject fluorescein intravenously and check the appearance of the dye in the anterior chamber with the lowest power of the slitlamp. The beam of light in the anterior chamber is reduced in intensity to such a degree that no green color can be observed. The current to the lamp is measured in amperes and the relationship between amperes and the absolute fluorescein concentration has been experimentally calibrated. Those figures for concentration of fluorescein and the time interval are recorded in graphs. The curves are characteristic for normal and pathologic conditions not only in the eyes but also for the body as a whole. (22 figures, references.)

Alice R. Deutsch.

Amsler, M., and Verrey, F. Fuchs's heterochromia and vascular fragility. *Ophthalmologica*, 1946, v. 31, Feb.-March, pp. 177-181.

After 1200 diagnostic punctures of the anterior chamber the authors were convinced that no clinical reaction follows this procedure. However in 18 patients with Fuchs's heterochromia a delicate hyphema regularly followed diagnostic paracentesis, probably as a result of local fragility of the vessels. It did not occur in six patients with heterochromia of the sympathetic type. (4 figures.)

Bonnet, P., Paufigue, L., and Bonamour. Central serous choroiditis. *Arch. d'Opht.*, 1946, v. 6, no. 2, pp. 129-144.

The authors state that the first example of this disease in France was described in 1934 and that since then

only a few scattered cases have been reported. They point out that the condition has been described under a variety of names, such as "vesicular edema of the macula," "detachment of the macula," "angioneurotic central retinitis," "macular edema with partial detachment of the vitreous," etc. They conclude that the ophthalmoscopic picture of the disease is extremely characteristic and agree that the name "central serous choroiditis," given to it by Japanese authors, adequately describes it. They believe that the choroidal nature of the condition is indicated by the insignificance of the visual symptoms which are usually due to a transient hyperopia.

After a complete description of the ophthalmoscopic appearance of the various stages of the disease, the authors describe the visual disturbances and field changes. They note that there is generally an oval paracentral scotoma above the fixation point and that the condition is generally bilateral although the second eye may not become involved for months or even years after the first. They note that the evolution of the choroiditis is extremely variable. Some heal in several weeks or months; in exceptional cases the condition may last for years. Recurrences are common. They note that the condition occurs most frequently in young adults, particularly men. In a discussion of etiology they discard syphilis as a factor but consider tuberculosis and focal infection as possible causes. They make no mention of the angiospastic theory of causation which has been advanced, particularly by Gifford. The article concludes with a detailed account of seven observations of the disease, well illustrated by one fundus plate in color and eight in black and white.

Phillips Thygeson.

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
904 Carew Tower, Cincinnati 2

News items should reach the editor by the 12th of the month

DEATHS

Dr. Louis Samuels Deitchman, Youngstown, Ohio, died September 4, 1946, aged 52 years.

Dr. George Baigerie Jobson, Franklin, Pennsylvania, died October 21, 1946, aged 77 years.

Dr. Frank Hermance Lasher, Brooklyn, New York, died in October, aged 63 years.

Dr. Simons Ravenel Lucas, Florence, South Carolina, died October 5, 1946, aged 61 years.

Dr. Charles B. Williams, Mineral Wells, Texas, died September 4, 1946, aged 72 years.

SOCIETIES

The Section of Ophthalmology, New York Academy of Medicine, announces its centennial meeting for Monday evening, March 17th, at 8:15 o'clock. The following papers will be presented: "Past and Future Progress in American Ophthalmology," by Dr. Derrick Vail, chairman, Department of Ophthalmology, Northwestern University, Chicago; "Notes on the History of Ophthalmology in Canada," Dr. John A. MacMillan, professor of ophthalmology, McGill University, Montreal; "History of the American Board of Ophthalmology," Dr. S. Judd Beach, secretary, American Board of Ophthalmology, Portland, Maine; and "New York's Contribution in the Development of Ophthalmology in This Country," Dr. Bernard Samuels, professor emeritus, Department of Ophthalmology, Cornell University Medical School, New York.

The third annual Sanford R. Gifford Memorial Lecture was given by Dr. Frederick C. Cordes, San Francisco, at the January 20th meeting of the Chicago Ophthalmological Society. Dr. Cordes' subject was: "Types of Congenital Cataracts."

At the 16th annual Spring Clinical Conference of the Dallas Southern Clinical Society, Dr. Francis Fralick, Ann Arbor, Michigan, and Dr. Leo H. Garland, San Francisco, will participate in the program. The meeting will open on March 17th and will continue through March 20th.

The Los Angeles Society of Ophthalmology and Otolaryngology has appointed the following officers for the year, 1947: president, Dr. William D. Donohoe; vice-president, Dr. Leland G. Hunnicutt; secretary-treasurer, Dr. K. C. Brandenburg; committeeman, Dr. Benton N. Colver. Meetings will be held the fourth Monday of

each month from September to May inclusive at 6 P.M. at the Los Angeles County Medical Association building, 1925 Wilshire Boulevard, Los Angeles.

MISCELLANEOUS

EYE BANK TO OPEN

A branch of the Eye Bank for Sight Restoration, Inc., is being opened at the Massachusetts Eye and Ear Infirmary, Boston. The bank is said to be the second such affiliated unit to be established. Persons donating their eyes after death for use in the corneal-transplant operation are asked not to make the gift a part of their wills, as a will is not effective immediately. Eyes must be enucleated by at least one hour after death. These medical technicalities make it necessary for the donor to be in a hospital at the time of death. For this reason the donation is made beforehand on a special blank sent by the eye bank on request.

SCHOLARSHIPS AWARDED

Four scholarships for advanced study of eye diseases at New York University College of Medicine were announced on November 27, 1946. The physicians selected for the \$500 awards are: Dr. Edward Danforth, Bainbridge, New York; Dr. Charles P. Goldsmith, Cata-sauqua, Pennsylvania; Dr. Jonathan L. Harris, Elberon, New Jersey, and Dr. Hugh E. McGhee, Jeffersonville, New York. All are postgraduate students at the College of Medicine, and are specializing in ophthalmology. The Eye Conservation Fund, Inc., of the New York Lions Club initiated the scholarship plan last spring with a gift of \$2,000 to the college. Mr. Ernest R. Fryxell, chairman of the Eye Conservation Fund, stated that the Lions Club will provide four scholarships annually for advanced study of eye diseases at New York University.

REFRESHER COURSE

The Department of Ophthalmology of Washington University School of Medicine, St. Louis, has announced that this year its annual Refresher Course will be given from June 9th through June 28th. The course is purely didactic, consisting of 98 hours of lectures. The subjects covered will include Corneal Diseases, Ocular Therapy, Surgery, Anatomy and Pathology, Embryology, Fever Therapy, Neuro-Ophthalmology, Headache, Allergy, Office and Laboratory Procedures, Industrial Ophthal-

mology, Radiology in Ophthalmology, and Dermatology in Ophthalmology.

The tuition is \$150.00 and the only prerequisite for those taking the course is a minimum of one year's training in Ophthalmology. The course is designed to refresh the busy ophthalmologist, to review candidates for the American Board of Ophthalmology examinations, and to enable the returned physician-veteran to reacquaint himself with his specialty.

Further details may be obtained from Richard G. Scobee, M.D., Director of Graduate Training in Ophthalmology, Washington University School of Medicine, 640 South Kingshighway Boulevard, St. Louis 10, Missouri.

GILL HOSPITAL COURSE

The first three days of the 20th annual Spring Graduate Course to be held at the Gill Memorial Eye, Ear, and Throat Hospital, Roanoke, Virginia, April 7th to 12th, will be devoted to subjects in the fields of Otolaryngology, Laryngology, Facio-Maxillary Surgery, Bronchoscopy, and Esophagoscopy. Beginning at 8 A.M. on Thursday, April 10th, the following program of particular interest to ophthalmologists will be presented.

Thursday, April 10th

8:00 to 9:00 A.M.

Clinic conducted by Dr. Eugene M. Blake, Clinical Professor of Ophthalmology, School of Medicine, Yale University, New Haven, Connecticut.
Subject: "The Pathology of Glaucoma."

9:00 to 10:00 A.M.

Clinic conducted by Dr. William T. Hunt, Associate Professor of Ophthalmology, Jefferson Medical College, Philadelphia, Pennsylvania.
Subject: "Essential Points in Routine Refraction."

10:00 to 11:00 A.M.

Clinic conducted by Dr. Arthur J. Bedell, Emeritus Professor of Ophthalmology, Albany Medical College, Albany, New York.
Subject: "Retinopathy of Hypertension."

11:00 to 12:00 A.M.

Clinic conducted by Dr. A. J. Ballantyne, Professor of Ophthalmology, Emeritus, Glasgow University, and President of Ophthalmological Society of the United Kingdom, Glasgow, Scotland.
Subject: "The Ocular Manifestations of Diabetes Mellitus."

12:00 to 1:00 P.M.

Clinic conducted by Dr. R. Townley Paton, Surgeon Director at the Manhattan Eye, Ear and Throat Hospital, New York, New York.
Subject: "Corneal Surgery, Particular Reference to Corneal Transplant." Illustrated with Lantern Slides and Motion Pictures.

1:00 to 2:30 P.M.—LUNCHEON AT HOTEL PATRICK HENRY

Clinic conducted by Dr. Arthur J. Bedell.
Subject: "Fundus Changes in Myopia."

2:30 to 3:30 P.M.

Clinic conducted by Dr. A. J. Ballantyne.
Subject: "Injuries of the Eye by Blunt Objects."

3:40 to 4:30 P.M.

Clinic conducted by Dr. William T. Hunt.
Subject: "Ocular Therapeutics."

4:30 to 5:30 P.M.

Clinic conducted by Dr. Eugene M. Blake.
Subject: "Choice of Operations in Glaucoma."

7:30 to 8:30 P.M.

Motion Picture Demonstration on "Surgery of the Eye," and presentation of Patients with Unusual Clinical Interest by Dr. E. G. Gill and the Staff of the Hospital.

8:30 to 9:30 P.M.

Clinic conducted by Dr. R. Townley Paton.
Subject: "Corneal Surgery, Particular Reference to Corneal Transplant." Illustrated with Lantern Slides and Motion Pictures. (Continued).

Friday, April 11th

8:00 to 8:40 A.M.

Clinic conducted by Dr. William P. Beetham, Surgeon at the Massachusetts Eye and Ear Infirmary, and Instructor in Ophthalmology, Harvard Medical School, Boston, Massachusetts.
Subject: "Diabetic Retinopathy."

8:40 to 9:20 A.M.

Clinic conducted by Dr. Eugene M. Blake
Subject: "Unilateral Exophthalmos."

9:20 to 10:05 A.M.

Clinic conducted by Dr. Arthur J. Bedell.
Subject: "Anomalies of the Fundus."

10:05 to 10:45 A.M.

Clinic conducted by Dr. A. J. Ballantyne.
Subject: "Birth Injuries of the Eye."

10:45 to 11:30 A.M.

Clinic conducted by Dr. Bernard Samuels, Professor of Ophthalmology, Emeritus, Cornell University Medical School, New York, New York.
Subject: "The Histology of the Eyeball with Special Reference to Inflammation and Surgery."

11:30 A.M. to 12:15 P.M.

Clinic conducted by Dr. Raymond E. Meek, Surgeon, New York Eye and Ear Infirmary, New York, New York.
Subject: Detachment of the Retina and the Surgical Treatment."

12:15 to 1:00 P.M.

Clinic conducted by Dr. William T. Hunt.
Subject: "The Management of the Lateral 'Phoria' and 'Tropia' Cases."

1:00 to 2:30 P.M.—LUNCHEON AT HOTEL PATRICK HENRY

Clinic conducted by Dr. Eugene M. Blake.
Subject: "Fundus Changes in Blood Dyscrasias."

2:30 to 3:15 P.M.

Clinic conducted by Dr. Bernard Samuels.
Subject: "The Histology of the Eyeball with Special Reference to Inflammation and Surgery." (Continued).

3:15 to 4:00 P.M.

Clinic conducted by Dr. A. J. Ballantyne.
Subject: "Some Intractable Diseases of the Cornea and Conjunctiva."

4:00 to 4:45 P.M.

Clinic conducted by Dr. Raymond E. Meek.
Subject: "Minor Surgery of the Eyelids and Conjunctiva."

4:45 to 5:30 P.M.

Clinic conducted by Dr. Arthur J. Bedell.

Subject: "Differential Diagnosis of Optic Neuritis from Papilledema."

7:30 to 8:30 P.M.

Clinic conducted by Dr. William P. Beetham.

Subject: "The Management of Some of the External Diseases of the Eye."

8:30 to 9:30 P.M.

Clinic conducted by Dr. William T. Hunt.

Subject: "The Near Point Examination."

Saturday, April 12th

8:00 to 9:00 A.M.

Clinic conducted by Dr. Raymond E. Meek.

Subject: "Cataract Extraction."

9:00 to 10:00 A.M.

Clinic conducted by Dr. William P. Beetham.

Subject: "Keratoconjunctivitis Sicca."

10:00 to 11:00 A.M.

Clinic conducted by Dr. Bernard Samuels.

Subject: "The Histology of the Eyeball with Special Reference to Inflammation and Surgery." (Continued).

11:00 to 12:00 A.M.

Clinic conducted by Dr. A. J. Ballantyne.

Subject: "The Etiology and Differential Diagnosis of Rapid Loss of Vision."

12:00 to 1:00 P.M.

Clinic conducted by Dr. Raymond E. Meek.

Subject: "The Surgical Management of Crossed Eyes."

1:00 to 2:30 P.M.—LUNCHEON AT HOTEL PATRICK HENRY

Clinic conducted by Dr. William P. Beetham.

Subject: "Crystalline Lens in Diabetes."

2:30 to 3:30 P.M.

Clinic conducted by Dr. Bernard Samuels.

Subject: "The Histology of the Eyeball with Special Reference to Inflammation and Surgery." (Continued).

3:30 to 4:30 P.M.

Clinic conducted by Dr. A. J. Ballantyne.

Subject: "The Non-Surgical Treatment of Cataract and of the Cataract Patient."

LOS ANGELES MID-WINTER CONVENTION

The 16th annual Mid-Winter Post-Graduate Clinical Convention in Ophthalmology and Otolaryngology was held January 20th to 31st in Los Angeles. Again this year, following the John Finch Barnhill tradition, the special course in "Applied Anatomy and Cadaver Surgery of the Head and Neck," was given from January 31st to February 4th.

The teaching staff included: Dr. Luzius Ruedi, Professor of Otolaryngology, University of Bern, Bern, Switzerland; Willi Furrer, Physicist in Acoustics, Federal Institute of Technology, Zurich, Switzerland; Dr. William L. Benedict and Dr. Henry P. Wagener, Mayo Clinic, Rochester, Minnesota; Dr. Sam E. Rob-

erts, University of Kansas, Kansas City, Missouri; Dr. Cecil S. O'Brien, University Hospital, Iowa City, Iowa; Dr. Alexander S. MacMillan, Massachusetts Eye and Ear Hospital, Boston; Dr. Samuel Salinger, Loyola University School of Medicine, Chicago; Dr. Kenneth C. Swan, University of Oregon Medical School, Portland; Dr. Dohrmann K. Pischel, Stanford University Medical School, San Francisco; Dr. David O. Harrington, University of California Medical School, San Francisco; Dr. Meyer Wiener, Washington University School of Medicine, Saint Louis; Dr. Rea E. Ashley, Stanford University Medical School, San Francisco; Dr. Ben H. Senturia, Washington University School of Medicine, Saint Louis; Dr. Clinton H. Thienes, University of Southern California, Los Angeles; Dr. Arthur C. Jones, Boise, Idaho; Dr. J. Mackenzie Brown, Los Angeles; Dr. Samuel A. Crooks, College of Medical Evangelists, Loma Linda, California; Dr. George C. Griffith, University of Southern California, Los Angeles; and Dr. Simon Jesberg, Los Angeles.

PERSONALS

Dr. Arthur Linksz gave a lecture and demonstration course in "Physiological and Geometrical Optics," at the Manhattan Eye, Ear, and Throat Hospital during January.

Dr. Wendell L. Hughes, Hempstead, New York, and Dr. Thomas D. Allen, Chicago, were among the speakers at the Postgraduate Medical Assembly of South Texas held in Houston, December 3 to 5, 1946.

DIRECTORY ANNOUNCEMENT

The American Board of Ophthalmology wishes to announce that a directory of all diplomates to January 1, 1947, will be published shortly. This directory will be arranged alphabetically and geographically. No biographical material will be included. Every effort will be made to make this directory accurate. Diplomates who have not already done so should notify the Board office, Cape Cottage, Maine, at once stating the name and address exactly as they wish them listed. Diplomates are also requested to keep the Board office informed of all changes of address so that the files can be kept up-to-date. The price for the directory will be three dollars, postpaid.

EXAMINATION DATES SET

The 1947 examinations of the American Board of Ophthalmology will be: Atlantic City, June 8th to 13th; Philadelphia, June 13th to 16th; Chicago, during the week of October 8th.

THE INFLUENCE OF HYPERSENSITIVITY ON ENDOGENOUS UVEAL DISEASE*

THE JACKSON MEMORIAL LECTURE

ALAN C. WOODS, M.D.

Baltimore, Maryland

It is my privilege tonight to deliver the Jackson Memorial Lecture. I am deeply appreciative of the high honor. I knew Dr. Jackson only as one of the great stalwarts of ophthalmology. He was one of the leaders of his day. To my mind he achieved his high position through the happy combination of many sterling qualities: a searching and analytical mind, a tireless and meticulous attention to detail—but details were never allowed to obscure his prime objective—a rugged honesty, and above all a kindly love for his fellow man. Although it was never my good fortune to serve under him, or be trained directly by him, no man who received his training in the period I did could help but be influenced for the better by Dr. Jackson's example and teachings. I freely acknowledge the debt.

The subject I have chosen for this lecture may at first glance appear somewhat foreign to the subjects in which Dr. Jackson was preëminently interested. Yet I excuse myself this seeming digression by recollecting a remark that Dr. Jackson once made to me. It was some years ago at a medical convention in Texas, when I had

delivered a lengthy and probably quite dull lecture on the relation of immunity in syphilis to syphilitic disease of the eye. After a perfunctory discussion had come to a close and the business had moved on to the next paper, Dr. Jackson sought me out and went out of his way to thank me for the paper. When I told him I was afraid it was a little foreign to the general interest of the audience, he told me frankly that he was well-aware of this, but he believed it was a healthy step to present such subjects to ophthalmologists, and that he, for one, trusted I would continue to do so. I have never forgotten his kindness or the sincerity of his advice. So with this pleasant memory, I have less temerity than I would otherwise have in discussing the subject of this paper—"The Influence of Hypersensitivity on Endogenous Uveal Disease."

Primarily there is an enormous confusion in the terminology of the hypersensitive reaction. This applies especially to the word "allergy." As used originally by von Pirquet it was defined as an altered reaction capacity of the organ. Its meaning was gradually extended by von Pirquet to include the general changes that occur with any antigen, even those which might not be the term ment of malignant disease. The minds of most

* Delivered on October 16, 1946, at the convention of the American Academy of Ophthalmology and Otolaryngology. From the Wilmer Ophthalmological Institute of the Johns Hopkins Hospital and University.

allergy is synonymous with acquired hypersensitiveness, it is used with a wide variety of meanings. Some authors limit its application to certain specific types of hypersensitivity; others use it to include all types of hypersensitiveness to foreign antigens, both bacterial or nonbacterial; and still others include in its meaning all forms of altered reaction capacity, including immunity. Rich has frankly stated that "the term 'allergy' has become so debauched by indiscriminate usage that it would be fortunate indeed if it could be dropped completely from the vocabulary of science."

This confusion of terminology is reflected in ophthalmic literature to such an extent that the terms hypersensitivity and allergy are used almost as scrap baskets or coveralls, being invoked to explain a variety of mysterious and often totally unrelated conditions for which there is no obvious explanation. Thus, we reach the final absurdity where we find a uveitis of unknown etiology attributed to an assumed allergy to an undiscovered virus! Scylla piled upon Charybdis!

Yet despite this indiscriminate and unjustified use of specific terms, and the definite gaps which exist in our knowledge, there is nevertheless a great fund of information on the hypersensitivity reaction and a generally accepted terminology. This knowledge and the terminology have recently been set forth in an orderly manner by Rich,¹ and since I know of no clearer exposition for our purposes here, we may follow his presentation.

THE TYPES OF HYPERSENSITIVITY

Two definite forms of hypersensitivity are recognized—the anaphylactic state and the hypersensitivity of infection. While there are many superficial resemblances between these two types, there are, nevertheless, differences so fundamental that they can be clearly differentiated.

I. ANAPHYLAXIS

A. The anaphylactic state is a form of hypersensitivity which results when foreign protein enters the tissues. When this hypersensitivity is once established, if small amounts of the same foreign protein are brought into contact with the sensitized tissues, either by intracutaneous injection or a patch test, a localized urticarial weal develops. If the antigen enters the circulation in sufficient quantities, various anaphylactic manifestations occur which include urticaria, "serum sickness," complete collapse, and even death. These symptoms come on promptly after the second exposure to the foreign protein and are caused by a spasmodic contraction of the involuntary smooth muscle and an increase in capillary permeability.

In addition to the local and general reactions, a focal reaction can occur in the anaphylactic type of hypersensitivity. Thus, if the initial or sensitizing injection of the foreign protein is given directly in the eye or in the cornea, and the second "intoxicating" injection is given intravenously, a sudden sharp inflammatory reaction may take place in the injected eye. This is a form of the "ophthalmic reaction" produced by protein antigens. It is manifestly due to a local increased reaction capacity of the eye, although it is not fully established to what degree this is due to a local vascular reaction dependent on the increased capillarity induced by the primary injection.

The anaphylactic type of hypersensitivity is probably produced exclusively by proteins. When it is apparently dependent on such nonprotein substances as inorganic chemicals, drugs, carbohydrates, and the like, the probable mechanism is a combination of the foreign, nonprotein material with the native protein of the body to form a new protein compound

which is foreign to the host. The anaphylactic manifestations result from an antigen-antibody reaction affecting primarily the fixed cells of the involuntary smooth muscle, the endothelium of the capillaries, and collagen fibers. While the anaphylactic reaction is characterized by edema, increased capillary permeability, congestion, hemorrhage, and spasm of the smooth muscle, it does not produce *per se* necrosis or death of the fixed cells. The anaphylactic type of hypersensitivity can be passively transferred, and is usually accompanied by the presence of specific precipitins in the body fluids.

B. *The Arthus phenomenon* is essentially an exaggerated local type of anaphylactic reaction. If foreign proteins, including the soluble portions of bacterial proteins, are introduced repeatedly and in small amounts into the tissues at intervals of several days instead of only once, an anaphylactic state will be produced. After sensitivity appears, the injections of the protein at first call forth the usual urticarial weal which vanishes in a few hours. But as these injections are continued, at last the introduction of a small amount of the foreign protein will produce an enduring local reaction characterized by hemorrhage, necrosis, and finally sloughing of the skin at the site of the reaction. In the case of bacterial protein, the Arthus type of hypersensitivity can be induced only by the injection of the soluble portions of the bacterial proteins, and when thus established, the phenomenon is elicited by the injection of the soluble bacterial proteins. While the Arthus phenomenon superficially resembles the reaction of the bacterial type of hypersensitivity, in that it may produce local necrosis, the fundamental mechanism is quite different. The local necrosis and death of the fixed cells in the Arthus phenomenon is not caused by a direct action on the extravascular tissue cells but is due

to an interference of their blood supply by thrombosis and rupture of the nutrient vessels.

C. *The "pollen" type* of hypersensitivity, which is produced not only by pollens but also by other protein agents, is quite similar to the usual anaphylactic type. It differs from it chiefly in its tendency especially to involve certain tissues, the bronchioles, nasal, and conjunctival mucous membranes, and in the fact that, although the antibody is demonstrated in the serum by passive transfer, its specific precipitins are ordinarily not demonstrable in the serum. In other respects—the immediate reaction, urticaria, erythema, smooth muscle spasms, and so forth—it is indistinguishable from the anaphylactic reaction. Since the differences are not fundamental, it may be regarded as a form of anaphylactic hypersensitivity.

II. THE HYPERSENSITIVITY OF INFECTION—BACTERIAL HYPERSENSITIVITY—THE TUBERCULIN TYPE OF HYPERSENSITIVITY

These terms are all synonymous and are used to describe a type of hypersensitivity quite different from the anaphylactic type in its various characteristics. This type of hypersensitivity can be readily induced by parenteral contact of the tissues with the living or dead bacteria, fungi, or filterable viruses, but not by any soluble antigens so far extracted from microorganisms. However, once it is established by contact with the bacterial bodies, reactions may be elicited by injection of the soluble bacterial proteins. The bacterial type of hypersensitivity is not characterized by the appearance of precipitins in the blood serum, and it cannot be passively transferred. The reactions elicited in the hypersensitive patient or experimental animal are: (a) a local, and (b) if the specific antigen is introduced in sufficient quantity, a systemic and (c) a focal reaction.

A. The local reaction. When the bacteria causing this hypersensitive state, or their soluble products, are introduced in the hypersensitive tissues, there is no immediate reaction, but a delayed reaction which comes on after some hours and reaches its maximum in 24 to 48 hours. The local reaction is characterized by erythema and edema, and in its extreme form by local tissue necrosis and sloughing. The cells of the body with the bacterial type of reaction are damaged by the contact of the antigen with the cell body, both in vitro and in vivo, and if the antigen-antibody reaction is sufficiently intense, the cells may be actually killed.

B. The systemic reaction. If the antigen is introduced in sufficient quantity, there may occur a severe systemic reaction, but unlike the anaphylactic reaction, this reaction is delayed and comes on gradually after some hours. In its mild form the systemic reaction is characterized by malaise, joint pains, fever, and so forth. In its severe form, death may ensue. The mechanism of this delayed reaction is not understood. It is variously believed that the antigen-antibody reaction may produce a toxin which damages the cells or that the cells undergo some bodily alteration which makes them capable of exerting an enzymlike activity on the antigen with the liberation of an irritant substance.

C. The focal reaction. In addition to the local and systemic reactions, a "focal" reaction may be induced if sufficient quantities of antigen are introduced. This focal reaction consists in the lighting up of any remote focus of infection caused by the specific infecting agent. Again it is a delayed reaction, coming on only after some hours.

The bacterial type of hypersensitivity differs from the anaphylactic type, therefore, in the fact that it can be produced only by introduction of the whole bacteria,

and not by soluble protein; therefore, it usually follows infection and vaccination with the bacterial body. The reaction to later introduction of the antigen is delayed and is accompanied by local inflammation, and often necrosis. There may occur also systemic and focal reactions. The site of the reaction is not limited to the involuntary, smooth-muscle capillary endothelium and collagen fibers, but is a widespread reaction in the sensitized cells of the body, and is associated with no demonstrable excess of free antibody in the circulation. The antigen-antibody reaction acts directly on the cells, causes cellular damage, and may cause death of the cells.

While anaphylactic and bacterial hypersensitivity are fundamentally different and in the main tend to be mutually exclusive, they can, nevertheless, occur together in the same individual or animal. Thus after bacterial infection, the infected body may develop not only the usual bacterial type of hypersensitivity from the protein of the bacterial body, but may also develop the anaphylactic type of sensitivity to the soluble products of the bacteria. For example, in pneumococcal infections the bacterial type of hypersensitivity to the pneumococcal protein may develop and also an anaphylactic type of hypersensitivity to the specific polysaccharide of the pneumococcus. Likewise in tuberculosis, while the injection of tuberculin or tuberculo-protein will not induce the tuberculin type of hypersensitivity, under certain conditions an anaphylactic type of sensitivity to tuberculin may develop.

III. IMMUNITY

There remains one last term to define—"Immunity." In general, immunity may be defined as an increased resistance to infection. This increased resistance may be either native to the organism or acquired by infection or inoculation. There are two main, recognized phases to the phenome-

non of immunity. The first is a humoral factor, due to the antibodies circulating in the blood stream and tissue fluids, which tend to fix, immobilize, and opsonize the bacteria, and in some infections may provoke extracellular destruction. The second is a cellular phase, centered chiefly in the mononuclear and phagocytic cells, which engulf the opsonized bacteria and either inhibit their proliferation or destroy them. In most infections, the important role of antibodies and phagocytes is readily demonstrable. In tuberculosis, the role of the circulating antibody is not as well-established as in various other infections, although it probably plays an important part.

The essential basic manifestations of acquired resistance are inhibition of the spread of bacteria and the suppression of their proliferation. In acute infections, this is accompanied by an actual destruction of the bacteria. In tuberculosis, however, while many bacilli are destroyed by the forces of acquired resistance, bacteriostasis with fixation and immobilization of the bacteria is prominent. Thus the bacilli may long remain viable, ready to proliferate and spread when the forces of resistance which hold them in check diminish and wane.

There has been much confusion on the relationship of allergy and immunity. For example, in tuberculosis, and indeed in many other infections, for years it was generally accepted that allergy (that is, a hypersensitive state) was responsible for the immunity (that is, acquired resistance)—that the hypersensitive reaction inhibited the spread of the invading specific bacteria and suppressed their proliferation. This idea was challenged by Rich and his co-workers in 1929.² In a long series of experiments by these and other investigators, it was clearly demonstrated that acquired resistance is in no way dependent on hypersensitivity. There is no actual

correlation between the two. Hypersensitive inflammation itself is incapable of preventing the spread of invading bacteria in the absence of acquired resistance. Effective acquired resistance can be established in the complete absence of any hypersensitive reaction.

Allergy (acquired hypersensitivity) and immunity (acquired resistance) should, therefore, be regarded as distinct phenomena. It should, however, be born in mind that as a result of infection or exposure to specific bacteria, both allergy and immunity tend to develop in the infected body. For example, both in clinical and experimental tuberculosis, the infected body usually develops a well-marked hypersensitivity to tuberculo-protein, while at the same time it shows a marked resistance to reinfection. This same holds true in other infections. The two phenomena, hypersensitivity and resistance, are, however, independent one of the other.

So much then for a brief summary of the clinical characteristics and fundamental differences of the two recognized types of hypersensitivity, a definition of acquired resistance or immunity, a word as to its mechanism, and its independence of any hypersensitive reaction. The main question before us is in what way the different types of hypersensitivity, both of which may follow infection, may influence endogenous uveal disease, how such influences may be suspected and detected, and how they may direct our therapeutic attack on the ocular disease.

TYPES OF ENDOGENOUS UVEITIS

Endogenous uveitis may conveniently be divided into three different groups: (1) sympathetic ophthalmia and the so-called endophthalmitis phacoanaphylactica; (2) the various metastatic purulent infections of the eye which arise from direct infection by blood-born bacteria;

(3) the usual nonpurulent uveitis, iritis, or choroiditis, which so often is recurrent, and comprises the greater percentage of all uveal disease.

While there is considerable evidence that a hypersensitive reaction is of paramount importance in both sympathetic ophthalmia and endophthalmitis phac-anaphylactica, the hypersensitivity in these diseases is dependent on the organ-specific proteins of the eye itself. This is a separate problem which has been amply discussed elsewhere, and is not germane to the present subject. Likewise, the various forms of metastatic ophthalmia, endophthalmitis, choroiditis spetica, and panophthalmitis, which result from the direct infection of the eye by bacteria carried by the blood stream, do not concern us in this discussion. In such direct infection with the usual pathogenic organisms, the process either becomes localized and walled-off with varying amounts of damage to the eye, or the infection spreads through the eye with the picture of a purulent ophthalmia. We are here concerned with the acute, the recurrent, and the chronic uveitis which constitute the usual clinical picture.

The older writers divided disease of the anterior uvea into "serous" and "plastic" iritis. To my mind, a much better terminology is "nongranulomatous" and "granulomatous," for these terms give an indication of the underlying pathologic process. In some instances it may be difficult or even impossible to make this differentiation, but as a rule the clinical pictures, as well as the underlying pathology of these two forms of inflammation, are quite different. The salient characteristics of these forms of uveitis are as follows.

Nongranulomatous uveitis. In the anterior uvea the onset is usually acute, rather than insidious, and ciliary congestion is marked with pronounced photophobia and lacrimation. The inflammatory

reaction in the iris is usually slight and is limited to loss of luster, blurring of the iris pattern, and dilatation of the capillaries. There are no nodules and but little tendency to the formation of posterior synechia unless there are repeated recurrences. The aqueous ray is usually intense due to the outpouring of serum, and there may even be a heavy gelatinous or fibrinous exudate in the anterior chamber. The deposits on the posterior surface of the cornea are small and pin-point and are composed chiefly of lymphocytes. Heavy, greasy exudates do not occur, and there is little or no tendency to capsular clouding of the lens. Koeppe nodules are never observed. The course of a nongranulomatous iritis is usually short, and the eyes usually recover with amazingly few residuæ. Only after repeated attacks is organic damage done to the eye.

A nongranulomatous inflammation in the posterior uvea is not so typical, and the diagnosis may be difficult or impossible. The general characteristics of a nongranulomatous choroiditis are slight clouding in the vitreous, fine muscae, wide-spread and intense subretinal edema, blurring of the neuroretinal outlines, obscuration of the physiologic cup, overfilling of the retinal-venous bed, and the absence of manifest or well-defined choroidal exudates. There is little tendency to actual tissue destruction and secondary gliosis.

Granulomatous uveitis. In the anterior uvea, the onset of the granulomatous iritis is usually insidious. The cellular reaction in the tissues is greater than the vascular reaction, and the ciliary congestion is not usually severe. Organic changes take place in the iris, with thickening of the stroma from cellular infiltration, with blurring of the iris pattern, and with loss of the normal luster. Well-defined nodules or tubercles on the surface of the iris, or diffuse localized thickenings suggesting nodules

deep in the iris stroma, are sometimes present. There is a marked tendency to the formation of posterior synechiae, with greasy exudates on the anterior capsule of the lens and capsular clouding. The keratic precipitates are of the so-called "mutton fat" variety, and histologically consist chiefly of epithelioid cells. Koeppe nodules, or accumulations of epithelioid cells at the pupillary border of the iris, are not uncommon. The aqueous ray may be intense. More often, however, it is rather mild.

In the posterior uvea, the granulomatous type of inflammation is usually marked by heavy veils and exudates in the vitreous. Manifest visible exudates in the choroid are the rule and they quickly involve the overlying retina. The subretinal edema may be diffuse, but it is usually localized and limited to the portion of the fundus adjacent to the exudates. The exudates are at first ill-defined. In some cases they spread and tend to involve the entire fundus with necrosis and destruction of the choroid and retina with later secondary gliosis. In other instances, they become quickly circumscribed and limited. In either case, the essential underlying pathologic process is tissue destruction with secondary overgrowth of glial tissue. When the process is localized, as in the well-known "circumscribed plastic chorioiditis," recurrences are common, and usually take place contiguous or at the site of the earlier lesion.

In the main, nongranulomatous and granulomatous uveitis tend to be mutually exclusive, the clinical picture usually following one or the other pattern. A few cases are encountered in which differentiation is difficult, characteristics of both types appear present in the same eye—acute inflammation followed by granulomatous changes. In these cases one has the impression that both processes are present together.

ETIOLOGY OF NONGRANULOMATOUS AND GRANULOMATOUS UVEITIS

There is a definite conflict of opinion on the etiology of endogenous uveitis. This is not remarkable since there are no fluids readily available for culture or animal inoculation, and no tissue for biopsy. The etiologic diagnosis is made on clinical observation, correlation of the clinical picture with the accumulated histologic material from similar eyes, and the general study of the patient. As a result, the literature reflects the individual clinical acumen and the knowledge of clinical-histologic correlation of the various reporters and their resources for medical study of the patient. While most authors agree that the various forms of uveal inflammation are infective in nature, they admit the clinical picture is quite different from the purulent reactions usually induced by bacterial metastasis. It is assumed that in some unknown way, either by passage through the body or by the local environment in the eye, the usual action of the infecting bacteria has become modified and an atypical picture results.

A great number of ophthalmologists believe that remote foci of infection are the most important cause of uveal disease, the disease in the eye resulting either from direct bacterial metastasis, or from toxins liberated from the focus of infection. While syphilis, tuberculosis, and other systemic diseases are recognized as causes of endogenous uveitis, they are considered less important. Another group of ophthalmologists places chief emphasis on tuberculosis and the other so-called infectious granulomas as etiologic factors. Still others express a middle-of-the-road opinion. There is little differentiation in the literature between the etiology of nongranulomatous and granulomatous uveitis. In fact, these terms are not in common usage. In general, however, the type of uveitis described here as nongranuloma-

tous is usually believed to be infective in nature, caused in one way or another, by the usual common pathogenic bacteria. The causes usually recognized for granulomatous disease are syphilis, tuberculosis, brucellosis, sarcoid, lymphogranuloma venereum, and certain fungus infections. It is quite probable that other etiologic agents, viruses and unrecognized bacterial infections, may produce a similar pathologic picture—for in an appreciable percentage of granulomatous uveitis, the most thorough medical survey reveals no recognizable cause.

In recent years, it has become fashionable to speak continually of allergy as influencing and actually causing endogenous uveitis, although rarely, if ever, does there appear to be any clear concept of the type of hypersensitive reaction involved, or the mechanism thereof. However, in many cases there appears to be a close correlation between the anaphylactic state, the hypersensitivity of bacterial infection, and the various manifestations of uveitis. It is not my intention to repeat here any of the statistical or experimental studies already published on the etiology of uveitis. Rather I would present to you my overall impression on the influence of the different types of hypersensitivity on endogenous uveitis, the methods used for the detection of the hypersensitive state, and what therapeutic measures may be used to combat it.

NONGRANULOMATOUS UVEITIS

The clearest-cut examples of non-granulomatous uveitis are the recurrent iris inflammations found in association with rheumatoid arthritis and old gonococcal infections. A similar acute iritis is sometimes found following acute systemic infections and is occasionally found in association with remote foci of infection, no other obvious cause being apparent. The ocular picture in these conditions

follows the same general pattern of non-granulomatous iritis already described. The course is sometimes so stormy that an inexperienced ophthalmologist might almost despair of saving the eye, but the disease finally subsides in a relatively short time with practically no organic damage to the eye. This type of iritis is remarkably resistant to ordinary forms of treatment. Certainly in my experience neither the sulfa drugs nor penicillin appear to influence the course of the disease, although some form of heat therapy, either nonspecific protein-therapy induced hyperpyrexia or prolonged local diathermy, appears of value.

Is this type of iritis due to the actual presence of living bacteria in the tissues of the eye? My contention is that in the recurrent nongranulomatous iritis associated with rheumatoid arthritis, old gonococcal infection, and sometimes with focal infection, there is no evidence whatsoever of living bacteria in the eyes. All the evidence, both clinical and experimental, is against such a supposition and points strongly to a hypersensitive reaction being the basic cause.

INFLUENCE OF HYPERSENSITIVITY IN NONGRANULOMATOUS UVEITIS

Acute iritis. Various authors (Kolmer,³ Berens, Rothbard, Angevine, and others⁴) have commented on the routinely negative blood cultures obtained in patients with acute iritis. It is true, however, that these cultures have been made after the outbreak of the iritis, and it is still conceivable that cultures immediately prior to the onset of the iritis might have been positive. However, such specimens of the aqueous as have been examined are sterile on culture and bacteriologic examination. In my experience, not only have the blood and aqueous cultures been sterile, but animal inoculations of the aqueous, either intraperitoneal in guinea pigs or in the

anterior chamber of a rabbit's eye, have all been negative.

Experimental investigations also argue against the actual presence of living bacteria in the eye and are in favor of a hypersensitive reaction being responsible for nongranulomatous iritis. Inoculation of the eye, either by direct injection in the aqueous or by intracarotid injection, of various strains of streptococci, pneumococci, and such organisms almost invariably results in a purulent ophthalmia which may progress up to destruction of the eye, according to the virulence of the invading organism. However, if the animals are sensitized to streptococci by repeated intracutaneous injections of living organisms, or by an infected agar implant, and the organisms are later brought into contact with the eye, a nonpurulent inflammatory reaction is produced. This was first described by Derick and Swift in 1929⁵ as "the ophthalmic reaction." These authors produced the ocular inflammation in sensitized animals by corneal scarification and instillation of the organisms in the conjunctival sac. This procedure has been amplified and modified by others. It has been clearly shown that a nonpurulent iritis may be produced in animals by various forms of systemic or local sensitization and by intoxication by intravenous injection of the antigen. Specific attention has been called to the fact that the iritis so produced corresponds clinically to that observed in humans. The picture is ciliary congestion, dilatation of the iridic vessels, contraction of the pupil, and even small exudates in the anterior chamber. The course is short and acute. The inflammatory process lasts several days only and then subsides without organic residua. Histologic examination of such eyes shows cellular infiltration of the iris, chiefly by lymphocytes and plasma cells (Brown⁶). If foreign proteins, such as heterologous serums, are

used as antigens, the ocular reaction is prompt. If bacterial antigens are used, the ocular reaction is usually delayed.

The most frequent positive findings in patients with nongranulomatous iritis are evidences of rheumatoid arthritis, an old gonococcal infection with a positive gonococcus complement-fixation reaction, a small active focus of infection, or a history of a recent acute infection of some type. Syphilis, tuberculosis, or other infectious granulomas are conspicuously absent. Positive reactions for bacterial hypersensitivity are the rule in these patients. The usual diagnostic procedures to detect such bacterial hypersensitivity are the intracutaneous injections of a 1:100 dilution of killed 24- to 48-hour cultures of various common organisms—alpha streptococci, beta streptococci, nonhemolytic streptococci, *H. influenza*, gonococci and finally a 1:100 dilution of mixed streptococci. The tests are read at the end of 15 minutes for an immediate anaphylactic type reaction to the soluble bacterial products. They are read again at 48 hours for the delayed tuberculinlike reactions to the protein of the bacterial body. The delayed tuberculinlike reaction is almost constantly present, although frequently, especially in the case with an acute fibrinous or gelatinous exudate in the anterior chamber, an immediate reaction to the soluble bacterial products is also present.

A word of caution must be given concerning the interpretation of the cutaneous reactions to bacterial antigens. The bacteria concerned are all common organisms to which the average individual has been constantly exposed for years, and reactivity to the intracutaneous inoculation of these organisms may occur in normal individuals, and may be especially marked after any acute infection. Before any diagnostic significance is attached to positive reactions, it should be estab-

lished: (1) that no other obvious cause can be found to which the uveitis is attributed; (2) that the patient shows an especial and unexplained hypersensitivity to specific organisms and not to all the bacteria tested; and (3) that the specific reactions shown are greater than are found in normal control individuals. With these reservations, in my experience, positive cutaneous reactions to such bacterial antigens are of diagnostic significance in nongranulomatous uveitis.

If the clinical nongranulomatous iritis under discussion is due to bacterial hypersensitivity, immediately it may be asked: What is the mechanism whereby the hypersensitive state is produced in the eyes and how does intoxication occur?

One can only surmise the mechanism through experimental analogy. Primarily, since the reaction is usually limited to the eye and only rarely accompanied by an urticaria or any pronounced general symptoms, one must assume an increased reaction capacity of the uveal tract. It has been clearly shown that such a local, increased-reaction capacity can be evoked experimentally by direct inoculation of the eye with the antigen. Therefore, to explain the clinical picture, it may be assumed that at some time the sensitizing bacteria have directly reached the eye. This may occur during the course of any transient acute bacteremia, which is certainly not uncommon, arising either from an acute general infection, from a remote infected focus, or by absorption from an infected, or even a normal, mucous membrane or cutaneous surface. The infecting dose of organism must be so small or of such low-grade virulence that the invading organisms are readily killed off by the bactericidal action of the ocular fluids, otherwise a purulent ophthalmia would result. If there is a repetition of such a bacteremia or later absorption of the soluble products of the bacterial body,

such antigens, when they reach the eye, encounter sensitized tissue and produce a hypersensitive reaction. This is the mechanism in the experimental animal, and from what is known of the frequency of transient bacteremias and infected mucous-membrane and cutaneous surfaces in man, it is a plausible explanation for the clinical phenomenon.

Occasionally the intoxicating bacterial protein may reach the eye from the exogenous source in such concentration that it may evoke symptoms in an eye not especially hypersensitive but only participating in the general tissue hypersensitivity. This is the case in the experimental ophthalmic reaction when the eyes are sensitized as part of the general tissue reaction, and intoxication is produced by local trauma of the eye and contact with the specific antigen. An analogous picture may occasionally occur clinically. Such a clinical phenomenon appeared to be the case in a physician whose eye was accidentally exogenously infected with streptococci. Two days later, he developed an acute nongranulomatous iritis. He was found to have a high degree of hypersensitivity to the specific invading streptococcus, and no other cause for the iritis could be found.

Is the hypersensitivity responsible for such a nongranulomatous iritis of the immediate anaphylactic type or of the delayed tuberculin type? In humans there is obviously no way of determining the time relation of the antigen entering the eye to the beginning of symptoms. In experimental animals, the evidence indicates the reaction is usually of the tuberculin type if bacterial antigens are employed. Thus Derick and Swift clearly showed that the ocular and general sensitivity produced by streptococcus antigens was of the delayed type, and the ophthalmic reaction came on 48 hours after the corneal scarification. Brown reported that

in his sensitized animals the first signs of iritis produced by intravenous injection of bacterial antigens were observed only after five hours. In MacLean's experiments, where the iritis was produced by intravenous intoxication, the reaction came on from 24 to 48 hours after the last intravenous injection. However, if foreign serums are used as the sensitizing antigens, the anaphylactic type of hypersensitivity results. This was first demonstrated by KümmeI in 1910,⁷ who found iridocyclitis with exudation in the anterior chamber six hours after intravenous injection of the foreign serum in animals previously sensitized by intraocular injection. However, this iritis was so marked at the end of six hours that it is obvious the first symptoms must have occurred much earlier. Such immediate reactions when foreign serums were used have been found by various other investigators (Wessely,⁸ Krusius⁹).

An anaphylactic type reaction in the eye was also shown by an experiment I did in 1916.¹⁰ In this experiment, the eyes of dogs sensitized by systemic injection of horse serum were later perfused with defibrinated blood. When horse serum was added to the perfusion fluid, there was an immediate contraction of the pupil, together with conjunctival and pericorneal congestion and the occurrence of petechial hemorrhages throughout the fundus. This appeared to be an example of spasmodic contraction of sensitized smooth muscle and of increased capillary permeability produced in eyes with the anaphylactic type of hypersensitivity on contact with the specific antigen.

It is apparent, therefore, that in experimental animals either the delayed bacterial type or the immediate anaphylactic type of hypersensitivity may be produced in the eye according to the type of sensitizing antigen employed. When patients are tested with bacterial antigens, the delayed

reaction is usually found, although frequently, especially in patients with acute exudation in the anterior chamber, there may also be an immediate reaction to the soluble bacterial products. It is a plausible hypothesis that such hypersensitivity to the soluble bacterial products may be responsible for the acute edematous reaction. It has already been noted that the initial attacks of nongranulomatous iritis rarely produce much appreciable damage to the eye, but after repeated attacks, damage and tissue destruction often occur. These later organic changes are probably the result of repeated minor insults caused by an antigen-antibody reaction on fixed cells with the bacterial type of hypersensitivity. However, it is an interesting speculation that in patients who also show an associated anaphylactic type of hypersensitivity the final damage done by repeated attacks may in part be a true Arthus phenomenon in the eye; that is, tissue destruction and secondary connective-tissue changes due to interference with the blood supply by thrombosis or rupture of the nutrient vessels.

This concept of nongranulomatous uveitis as a bacterial-hypersensitivity phenomenon obviously suggests desensitization as a therapeutic procedure. Such desensitization should be as specific as possible. In the case of streptococci, there are now some 40 odd antigenically different strains known. The specific strains responsible for the hypersensitive state should be determined, if possible. This is done by individual cutaneous testing with all available strains. Many laboratories, especially those interested in vaccine therapy for rheumatoid arthritis, have a large number, although usually not all, of the known strains on hand, which may be used for the determination of specific sensitivity. After the demonstration of cutaneous hypersensitivity to stock or mixed strains of streptococci, the patient

should be tested against all individual strains obtainable, and the final vaccine should be prepared from the specific strain or strains to which the patient shows the most pronounced sensitivity, rather than from a stock or mixed strain which may, however, be antigenically related.

The route of administration of streptococcus vaccine appears of some importance. It has been shown that the subcutaneous administration of streptococcus vaccine tends to increase and maintain the sensitivity rather than diminish it, while the converse is true when the vaccine is administered intravenously. Wainwright¹¹ has utilized this principle in the treatment of rheumatoid arthritis with streptococcus vaccine, giving the vaccine intravenously. This idea has been followed in the streptococcus vaccine therapy of the recurrent iritis associated with rheumatoid arthritis. The initial dose of the vaccine must be small and cautiously given, otherwise focal reactions will be produced in the eye. The results of such treatment have been gratifying. There are now in records of the Wilmer Institute a number of patients, all with the history of recurrent nongranulomatous iritis associated with rheumatoid arthritis, who have been under intravenous, streptococcus-vaccine therapy for periods up to seven years. The general result is the same—diminishing frequency and then freedom from attacks during the period of treatment. When treatment is stopped, however, recurrences in two to four months are not infrequent. Synchronous with the irido-relapse, there is usually a recurrence of the cutaneous sensitivity which had previously diminished or disappeared under the vaccine therapy. In several of these patients, continued weekly injections of the streptococcus vaccine appear to be the price of freedom from the attacks of iritis.

My only other experience with vaccine therapy for nongranulomatous iritis is

with recurrent gonococcal iritis accompanied with a positive history of infection, a positive complement-fixation test with gonococcal antigens, and a positive skin test to gonococcus vaccine. Here the vaccine has usually been given subcutaneously. The majority of patients so treated appear to be benefited in the sense that the attacks occur at much longer intervals and are much less severe. The results, however, have not been as striking as those obtained with the streptococcus vaccine in iritis associated with rheumatoid arthritis.

Choroiditis. By far the great majority of cases of choroiditis belong to the granulomatous type, characterized by exudation, tissue destruction, and secondary gliosis. While granulomatous disease appears with equal frequency in the anterior and posterior uvea, nongranulomatous disease has an undoubted predilection for the anterior uvea. Why this should be so is not clear. Occasionally, cases of choroiditis are encountered in which the salient symptoms are marked subretinal edema, and an absence of visible exudates and tissue destruction. These cases usually run a short course and are not followed by secondary gliosis. I have seen several such cases which were clearly focal reactions following the diagnostic injection of injudicious amounts of tuberculin. I have not seen such cases in which a bacterial hypersensitivity to other organisms was demonstrated. If such cases occur, they are certainly rare. All that can be said, following the arguments presented for a hypersensitive nongranulomatous iritis, is that such a nongranulomatous choroiditis from bacterial hypersensitivity is a possible clinical entity, and careful observation may establish such a mechanism.

GRANULOMATOUS UVEITIS

Granulomatous disease affects both the

iris and choroid, and often the entire uveal tract. It may, therefore, be discussed as a single entity.

The evidence indicates that in granulomatous uveitis the various recognized, specific etiologic agents are present in living form in the uveal tract. In syphilis, this is certainly true. In tuberculosis, it is likewise almost certainly true. In experimental ocular tuberculosis, practically all the various clinical manifestations can be produced by inoculation of the eyes of properly prepared animals, and living bacilli can usually be demonstrated in such eyes long after all symptoms have disappeared. In the occasional spontaneous uveitis that occurs in animals systemically infected with tuberculosis, the bacilli can be demonstrated in the eye either by bacterial stains or by animal inoculation of the diseased eye. In some forms of clinical ocular tuberculosis, the bacilli can frequently be demonstrated by bacterial stains of sectioned eyes, and the inability sometimes to find them can probably be explained either on technical grounds or on the chronicity of the disease with final healing and consequent destruction of the bacteria. In lymphogranuloma venereum, the living virus is almost undoubtedly present in the ocular lesions, for in the characteristic oculoglandular conjunctivitis that frequently complicates the general infection the virus has been recovered from the conjunctival scrapings. In brucellosis, the bacteriologic evidence at hand indicates that living organisms are probably present in the ocular lesions, although their presence has not yet been conclusively demonstrated beyond shadow of doubt. Nothing can be said of sarcoid, for the specific causative agent, whatever it may be, has never been isolated and the etiology of the disease is a complete mystery. Nothing can be said of other possible etiologic agents until they are identified.

INFLUENCE OF HYPERSENSITIVITY IN GRANULOMATOUS UVEITIS

In syphilis a great deal is known of the influence of specific immunity on the occurrence of syphilitic lesions. The effect of such immunity on syphilitic lesions of the eye has been discussed elsewhere and need not be repeated here. Little or nothing is actually known of the effect of specific hypersensitivity on syphilitic lesions. The reason for this is that no antigen or syphilitic material has ever been discovered with which specific hypersensitivity can be effectively demonstrated. Any hypotheses on the subject are therefore, only by analogy and are little more than idle surmise. In brucellosis, the experimental study of the general disease and of ocular brucellosis, in particular, has not yet been sufficiently extended to warrant any conclusions on the influence of general or local hypersensitivity on the course of the lesions. What evidence there is indicates that both immunity and hypersensitivity may profoundly affect the course of the general and local disease.

There is little or no clinical or experimental knowledge of the effect of hypersensitivity and immunity in the uveitis produced by viruses and fungi. What we do understand, with reasonable clarity and certainty, is the influence of both hypersensitivity and immunity on the lesions caused by the tubercle bacillus. In this regard, both the general lesions of the disease and the lesions of ocular tuberculosis follow the same pattern. We may therefore use tuberculosis as an example to illustrate the effect of hypersensitivity and immunity in granulomatous uveitis.

✓ The instillation of tuberculin in an already tuberculous eye may at times evoke a crop of phlyectenules, and the systemic injection of excessive amounts of tuberculin may likewise cause a focal inflammatory reaction in a tuberculous eye. These are true hypersensitive reactions, they are

dependent on the previous sensitization of the eye by invasion of the eye by the bacilli, and are an example of the delayed reaction produced by the soluble portion of the tubercle bacilli when the eye has been previously sensitized by the protein of the bacterial body. Tuberculous lesions may also be produced by the injection of killed tubercle bacilli, and even by their fractions—tuberculolipides and especially tuberculophosphatide. But these lesions are nonprogressive, even in the nonimmune animal, and their extent is directly proportional to the number of bacilli or the quantity of lipides injected. Such lesions do not concern us clinically. The point to be emphasized is that true progressive tuberculous lesions, with cellular infiltration of lymphocytes and epithelioid cells, tubercle formation, and caseation or encapsulation, are produced only by the actual invasion of the eye with tubercle bacilli and the presence of the bacilli in the eye in living form. The course of the lesions resulting from such bacterial invasion is profoundly modified by the factors of immunity and tissue hypersensitivity, but hypersensitivity to tuberculo-protein *per se* does not produce characteristic tuberculous lesions, notwithstanding the innumerable statements to the contrary with which ophthalmic literature fairly bristles. It is, therefore, incorrect to speak of "allergic tuberculous lesions;" or to say that certain specific ocular lesions (excluding phlyctenules and focal reactions) are "caused by allergy." The lesions are caused by invasion of the ocular tissues by the tubercle bacilli. The course and character of the lesions is modified and influenced by the factors of immunity and tissue hypersensitivity.

In what manner do hypersensitivity and immunity modify and influence the course of tuberculous lesions? This can best be illustrated by following the course of ocular tuberculosis in experimental ani-

mals, for here the picture simulates the clinical disease with amazing faithfulness.

If a normal nontuberculous rabbit is inoculated in the anterior chamber with virulent human tubercle bacilli, there is practically no immediate reaction. With the usual dose of organisms, small hard tubercles develop on the iris, in the cornea, and in the ciliary body in about two weeks. There is only a minimum inflammatory reaction. As the bacilli propagate and the tuberculous lesions multiply, the picture gradually changes. In about four to six weeks after inoculation, the inflammatory reaction increases; evidences of caseation appear with necrosis of the involved cornea and sclera; and somewhere about the 12th week the eyes usually perforate. If sample rabbits from such an experiment are tested from time to time for sensitivity of the eye to tuberculo-protein, it is found that the development of acute inflammation, caseation, and necrosis parallels the development of the hypersensitivity to the tuberculo-protein.

When the eyes of rabbits which have had a previous systemic tuberculosis (immune-allergic animals) are similarly inoculated, the picture is quite different. As a result of the old systemic infection, such rabbits have developed a generalized hypersensitivity of all the body tissues, including the eyes, to tuberculin. At the same time they have developed a greatly increased resistance to reinfection, although there is no relation between the hypersensitivity and the immunity. This resistance to reinfection may be so great that it requires many times the dose given normal rabbits to produce ocular lesions. When the necessary dose of bacilli is injected into the anterior chamber of these rabbits, an acute inflammatory reaction develops in 24 to 48 hours. This reaction lasts for several days. This is the local reaction to the tuberculin in the inoculum and is dependent on the ocular hyper-

sensitivity which has occurred as part of the general sensitization. This reaction subsides within a week, and thereafter there is a latent period of several weeks without symptoms. Hard tubercles then slowly develop in the iris, cornea, and ciliary body. However, these lesions do not increase in size nor progress to the extent they do in the normal rabbit. The inflammatory reaction is usually of low degree, there is very little caseation and necrosis, and these eyes rarely if ever perforate. The entire course of the local disease is restrained, and after three to four months, the process burns out with moderate scarring and damage to the eye. If the eyes of sample rabbits from a series of such animals are examined for local reactivity to tuberculo-protein, it will be found that there is only a very moderate increase in the local reactivity and the degree of inflammatory reaction and tissue destruction in the eyes parallels the degree of local hypersensitivity.

This fundamental principle, that inflammation, caseation, and necrosis parallel the degree of local-tissue reactivity to tuberculo-protein, can be illustrated in various other experiments. For example, rabbits develop varying degrees of hypersensitivity to tuberculo-protein after systemic infection. Thus when the eyes of animals with a low sensitivity are inoculated with tubercle bacilli only minimal inflammatory lesions result; while if the eyes of animals with high sensitivity are selected, much more pronounced inflammatory symptoms result. Similarly, if hypersensitive rabbits are desensitized with tuberculin prior to inoculation of the eyes, there is almost no inflammatory reaction to the tuberculin in the inoculum, and any later inflammation or caseation is proportional to the degree of local hypersensitivity which the eyes later again develop as a result of the local infection.

Just as different rabbits develop differ-

ent degrees of tissue hypersensitivity after systemic infection, they likewise develop different degrees of immunity. When a series of rabbits with systemic tuberculosis is inoculated in the eyes, some develop no symptoms whatsoever, while others develop ocular lesions after widely varying inoculation periods. Some require huge doses of bacilli to evoke ocular lesions, while others develop lesions after a relatively small dose of bacilli. In rabbits with low immunity, the tuberculous lesions usually spread throughout the eye, and with the spread of the lesions increased local hypersensitivity develops. As a consequence, there is an increased inflammatory reaction with greater tendency to caseation and necrosis. In rabbits with high immunity, the lesions are much smaller, show little tendency to spread, run a shorter course, and heal comparatively quickly.

Thus by studying large numbers of systemically infected rabbits which have later been inoculated in the eye, the factors that modify the course and character of ocular lesions become apparent. If the immunity is high and the tissue hypersensitivity is low, minimal lesions result, with little inflammatory reaction, and such lesions usually become quickly encapsulated. On the other hand if the immunity is low and the tissue hypersensitivity is high, spreading inflammatory lesions result, with caseation and necrosis. Various fluctuations between these two extremes produce the intermediate chronic type of reaction.

I have spoken of "local" tissue hypersensitivity, meaning the hypersensitivity of the tissues of the eye and not the general cutaneous or systemic hypersensitivity. In experimental animals, the local ocular sensitivity can be readily determined by injecting measured amounts of tuberculin or purified protein derivative into the eye, estimating the ensuing in-

flammatory reaction, then enucleating the eye and evaluating the histologic reaction. Unfortunately in patients, there is no safe way of estimating this ocular sensitivity. From experimental studies, it has been clearly demonstrated that in a tuberculous eye, there may be no parallelism between the local ocular reactivity to tuberculin and the cutaneous reactivity. The local disease in the eye may produce a high degree of local ocular reactivity, while the cutaneous sensitivity remains low. The tuberculous process in the scleral envelope is insufficient to affect profoundly the cutaneous sensitivity. However, if the cutaneous sensitivity is high, the ocular sensitivity is likewise high, for the eye participates in the general tissue reaction.

In the study of clinical ocular tuberculosis, we are handicapped by this inability to determine the degree of local ocular hypersensitivity. All that can be determined is the degree of cutaneous sensitivity. If this is high, then the ocular sensitivity can safely be assumed to be high. But if the cutaneous sensitivity is low, the ocular sensitivity may be much higher, influenced by the local disease. The degree of ocular sensitivity in such cases can be estimated only by studying the degree of inflammatory reaction, and searching for evidences of caseation and necrosis, which are the concomitants of local tissue sensitivity. Yet, despite this handicap, when cases of clinical ocular tuberculosis are studied over a period of years, they appear to follow the same general pattern of experimental lesions.

Thus in infants and children, ocular tuberculosis is characterized usually by a high degree of hypersensitivity and a low immunity. A tuberculous choroiditis in a child or in the Negro (in whom the tuberculous process generally is of the infantile type) usually spreads rapidly and tends to involve the entire fundus with extensive caseation and tissue destruction.

Tuberculosis of the anterior uvea usually is of the same severe type. In children with a miliary tuberculosis, tubercles on the iris and choroid are not uncommon. These children may be so ill that they are unable to develop any tissue response to the invading bacilli, and there may be little inflammatory reaction around the tubercles. But if these children are hypersensitive or if they do not die from the generalized infection and bacillemia, and later develop hypersensitivity, then the iris tubercles undergo an inflammatory reaction, increase in size, coalesce, and there is caseation, tissue necrosis, and often actual perforation of the eye.

In young adults or older patients in whom a general systemic immunity of varying degree has developed but in whom tissue hypersensitivity may still be high, tuberculous lesions such as sclero-keratitis run a typical course of attacks of acute inflammation, but tend to be walled-off, self-limited, only to recur again and again as the resistance fluctuates. Tuberculous periphlebitis with the recurrent vitreous hemorrhages is usually a disease of early adolescent life and is usually accompanied by a high degree of sensitivity to tuberculin.

What histologic evidence there is indicates that the so-called "circumscribed plastic choroiditis" is a localized tuberculous lesion. It occurs usually in adults and is characterized by single exudates near the posterior pole of the eye which quickly become circumscribed and walled-off. In such patients the cutaneous sensitivity to tuberculin is usually moderate or low. The course of the choroidal lesion, with an absence of surrounding inflammatory reaction, with rapid walling-off and gliosis, suggests the local tissue sensitivity is also low, while the immunity of the patient is high. In short, in individuals with high sensitivity and low immunity, the lesions of ocular tuberculosis are

characterized by high inflammation, invasive tendency, and tissue destruction; while in individuals with low sensitivity and a well-developed immunity, the lesions tend to be minimal, are attended with little inflammatory reaction, and are rapidly encapsulated. The long drawn-out, chronic, fluctuating lesions are indicative of both moderate resistance and hypersensitivity.

If we grasp the underlying principles which determine the character and course of tuberculous lesions of the eye, the therapeutic indications are clear. They are: (1) to enhance the resistance of the patient to the disease; and (2) to abolish the tissue hypersensitivity. Unfortunately, there is no direct way to increase the immunity, for artificial immunization is still much of a sought-for dream. General hygienic measures are still our main resource. Desensitization with tuberculin is a long and laborious process, often difficult and sometimes impossible to accomplish, and when once accomplished can usually be maintained only by continued tuberculin treatment over years. Yet unsatisfactory as these procedures may be, they are still the cornerstones of the treatment of ocular tuberculosis.

CONCLUSIONS

I have endeavored to point out the clinical differences between two types of uveal disease, nongranulomatous and granulomatous. Both types are dependent on invasion of the eye, at one time or another, by living bacteria, but the pathogenesis and character of the lesions in these two types of uveal-disease, appear to be quite different. In the nongranulomatous type, the primary invasion of the eye is probably by organisms either of low virulence or in small numbers. The result is that they are destroyed by the normal bacteriocidal action of the ocular fluids. This primary invasion produces either in-

significant lesions or no lesions at all, but it does produce a local hypersensitivity of the ocular tissues either to the bacterial protein or to the soluble bacterial products. This hypersensitivity may be of the bacterial type, or of both the anaphylactic and bacterial type. When the bacterial antigens again reach the eye, either through reinfection or absorption from an infected focus or even a normal cutaneous or mucous-membrane surface, there results a hypersensitive reaction in the eye. This reaction is produced either by organisms which do not proliferate, or by their bacterial products. In either event, the reaction is essentially an evanescent one and is characterized by an intense vascular congestion and a minimum of tissue damage—the picture of a non-granulomatous uveitis.

In the granulomatous type of uveitis, the mechanism is quite different. The organisms reaching the eye are not destroyed, but remain viable in the ocular tissues, and by their presence, proliferation, and inherent toxicity, produce local lesions in the eye. The character of the resulting lesion is profoundly modified and influenced by the factors of local hypersensitivity and general immunity. The proliferation of the organisms in the eye produces a local hypersensitivity to the bacterial products. This hypersensitivity is of the bacterial type, and a reaction between the hypersensitive tissue and the bacterial products may thereafter result. If the proliferation of the bacteria is not restrained by the forces of immunity, this hypersensitive reaction will be progressive, characterized by inflammation, caseation, necrosis, tissue destruction, and often a compensatory overgrowth of granulomatous tissue. If however, there is present either a natural or an acquired resistance to the infection, the proliferation of the bacteria is restrained and the reaction is minimal.

I have used tuberculosis as an example to illustrate the influence of hypersensitivity and immunity in granulomatous uveitis. I realize fully that there are many peculiarities of the tubercle bacillus which differentiate it sharply from nonacid-fast pathogenic organisms and open the door for the criticism that the general laws which influence tuberculous lesions may not be applicable to disease caused by other bacteria. Yet, I do not believe this to be true. I believe the same general principles of resistance to infection and tissue hypersensitivity, which have been so extensively studied in tuberculosis, will likewise apply, with minor variations, to the lesions found in other infectious granulomatous diseases. This can be de-

termined only through further animal experimentation and clinical observation. Our knowledge of resistance and hypersensitivity and their influence on local and systemic disease has broadened greatly in the last few decades, but there is still much to be learned. If we approach the problem of the etiology of uveitis with an orderly concept of the underlying principles of infection, resistance, and hypersensitivity, as they are now known and may later be amplified, I believe the influences of these fundamental tissue reactions will be demonstrated, not only for the present known causes of uveal disease, but also for other etiologic factors which yet remain to be discovered.

A CONTRIBUTION TO THE KNOWLEDGE OF OCULAR SIDEROSIS AND POSTERIOR DEGENERATIVE PANNUS*

PART I OF THE RESEARCH IN INDUSTRIAL OPHTHALMOLOGY

ARNOLD LOEWENSTEIN, M.D., AND JOHN FOSTER, M.D.

Leeds, England

It has been generally accepted, since Leber published his classical investigations, that an intraocular iron splinter is partly converted by the carbonic acid of ocular fluids into one or more diffusible compounds.

When the experiment is carried out on rabbits' eyes, the compound, bicarbonate of suboxide of iron, is precipitated (possibly by oxygen in the tissues) both near the foreign body (direct siderosis), and also at a distance (indirect siderosis).

Even the best microscopic reagent at our disposal (Perls's hydrochloric acid and potassium ferrocyanide) does not reveal all the iron present, as a further portion combined with protein is not stained as Prussian blue.

Examination of a siderotic retina, stained in bulk by Perls's method, reveals not only beautiful blue patches, but a rash of brown patches which may contain masked iron, melanin, or both.

Certain tissues of the eye may have a selective affinity for different chemical compounds. Elastic fibers, for instance, are argyrophil, as Loewenstein (1941) has shown in the tissue of the argyrotic tear sac; copper, too, is localized to certain tissues of the globe in chalcosis bulbi; while Wolff (1934) has suggested that all living cells will absorb iron in varying degrees, glass membranes being the least absorptive of all.

The literature on siderosis is already extensive, and we only feel justified in

publishing our case in detail, because we have observed tissue changes which lead to general conclusions. The discovery of some of these changes is due to the employment of methods frequently neglected by the majority of investigators.

The patient, a fitter aged 40 years, who had never worked as a smith or been unduly exposed by his occupation to infra-red radiation, was first seen in 1935. He was then applying for a Civil Service post, and stated that his left eye had been blinded by an intraocular steel splinter which was "removed by operation" shortly after the accident in 1923. The eye showed no visible perforating scar, but had characteristic rusty changes in the iris, and brownish spots at the anterior surface of the cataractous lens. The vision amounted to good projection of light only.

The patient was told that excision might eventually be necessary, but that this would not be essential so long as the eye was free from inflammation. The eye remained quiet until 1944, when he had attacks of pain lasting a week at a time.

He finally came for treatment in September, 1945, with a severe iritis and hypopyon, which had lasted three weeks. The eye was then acutely inflamed and blind. The cornea was edematous, the anterior chamber contained a hypopyon and a supernatant brownish fluid. The iris, a deeper brown than before, was tremulous—the cataract having disappeared from the pupil.

The right eye had at all times been completely normal. After excision under local anesthesia, the siderotic eye was fixed in formalin.

* From the Tennent Institute, Glasgow, Prof. W. J. B. Riddell, Director. Sponsored by the W. H. Ross Foundation (Scotland) for the study and prevention of blindness.

Frontal division of the eye revealed an opaque and shrunken lens floating freely in a fluid vitreous. A metallic foreign body was firmly embedded (6 mm. from the limbus) as is shown in the natural size

the site of water-clear cysts, whose elevation was clearly demonstrated by the narrow beam.

Many pieces of the peripheral retina and choroid were excised for examina-

Fig. 1 (Loewenstein and Foster). Stereophotograph of the foreign body in situ. Anterior half of the eye.

stereophoto (fig. 1). The visible portion measured $0.75 \times 2.5 \times 2$ mm. The foreign body was removed without difficulty prior to embedding the eye in celloidin. An oval defect of the iris tissue was revealed by diaphanoscopy, marking the track of the foreign body into the interior of the globe.

Slitlamp examination of the posterior half of the opened eye showed thin retinal vessels and that the macular area was

tion in bulk, while the horizontal area, about 8 mm. broad, containing the disc and macula, was embedded in celloidin.

The corneal epithelium was abraded at many points (artefact), and Bowman's membrane was marked by dark round corpuscles in the hematoxylin and eosin slides. In the periphery these were isodiametric about 0.25 to 0.5μ . Toward the center the granules were thicker about 1μ in diameter, and occurred more frequently (fig. 2). A few granules were found in the superior corneal lamellas. Toward the epithelium the granules were generally denser than they were basally (fig. 2).

Perls's Prussian-blue reaction showed a fine blue haze in the epithelium and that these corpuscles were ferric. Their size was the same in sections stained by hematoxylin, Perls's method, or by the two methods combined.

The corneal corpuscles were clearly visible and neither shrunken nor edematous. The corneal

Fig. 2 (Loewenstein and Foster). Siderosis of Bowman's membrane.

corpuscles, Descemet's membrane, and the endothelium were iron free and normal, if one excepts a few macrophages and neutrophil leukocytes adhering to the endothelium.

The hypopyon contained plasma cells in addition to macrophages, neutrophil leukocytes, and pigment, both free and in macrophages. A moderate number of eosinophils were present (fig. 3). While the macrophages contained both Prussian-blue particles and a brownish-yellow pigment, the reticulum cells around Schlemm's canal contained a modest amount of blue particles only.

Some of the limbus vessels were "cuffed." The trabeculum contained a scattered mass of red blood corpuscles, which stained well with eosin.

There was an intensive patchy infiltra-

tion of the iris tissue, and the vessels were dilated and engorged. The infiltration consisted almost entirely of plasma cells, although some macrophages with a coarsely granular protoplasm were found superficially.

In the ironstained slides, a large amount of blue granular tissue could be found between the pigmented layer and the clearly visible dilator fibers, infiltrating the latter. Some of the latter showed iron granules as well.

The ciliary body showed far less inflammatory cellular infiltration. With Perls's reaction, there were many fibroblasts filled with blue granules. There were polygonal reticulum cells in the corpus ciliare containing even larger granules. A considerable amount of iron was free in this area, and large poly-

hedric cells like mast cells were crammed with dark-blue masses. Both the pigmented and unpigmented epithelial layers showed patches of iron at certain places, and a fine blue powder at others. The ciliary body contained a multitude of

foreign-body giant cells were found. Here were iron-laden fibroblasts, neutrophil leukocytes, and macrophages, some of which had engulfed iron material.

At the side where the foreign body was situated, no trace of zonular fibers could

Fig. 5 (Loewenstein and Foster). Lens capsule, Perl's reaction (oil immersion). The capsule is iron free, as is also the split-off lamella. ragged blue patches. Some swollen cells with round nuclei on the posterior iris surface contained dark, round inclusions.

At the site of the foreign body the scleral fibers were irregular, and broken up plaques—Fe+Ca—were present (fig. 4). These were probably broken in the removal of the foreign body prior to the embedding. Between these layers an eosin-red, hyaline mass was present, extending into the vitreous space. No for-

be found; while at the opposite side, some broken-up, glassy, preretinal fibers were visible in a position suggesting that they corresponded to zonular fibers. The space between these glassy fibers was filled with small, thin cells and with macrophages containing small brown and (iron) blue bodies.

The freely movable, shrunken, and markedly deformed lens was embedded separately in paraffin, and sectioned me-

tionally. The subcapsular epithelial nuclei were irregularly distributed and broken up (fig. 5). A lens capsule of variable thickness covered the entire lens and was split most markedly where it was the thickest, presumably the anterior pole (figs. 6a and 6b). There were brownish granular masses between the capsule and the irregular flat nuclei of the epithelium. A layer of subepithelial tissue less than 8μ thick stained eosin red, but the remainder of the lens matter was a loose purple-stained granular mass.

The lens capsule showed under high-power magnification ($\times 1,350$) an anterior lamella of a purplish-pink color (fig. 6a) which could be seen overlying another lamella of equal thickness but unstained. The split membrane (fig. 6c) was continuous with the more anterior of these layers. Where this membrane floated in front of the lens, this unstained lamella was absent from the lens itself.

The choroidal vessels were broader than usual, but there was no sign of posterior-choroidal infiltration except toward the periphery, where the choroid consisted of pigmented scar tissue fused with the retina. There were some groups of plasma cells and thickening of the pigment of the suprachoroid. The hexagonal cells were paler than normal, and the pigment, which was scattered in the central area, was aggregated toward the periphery. There was no visible break in Bruch's membrane which was very thick near the disc. The opacity of this thick area suggested the fatty degeneration frequently found in degenerated eyes.

The wavy appearance of the thickened, inner-limiting membrane near the macular area was not just a postmortem appearance, as the crests of the waves were linked by membranes consisting of fibroblasts, lymphocytes, and macrophages (fig. 7). The valleys between these crests

were filled by neutrophil leukocytes, red blood corpuscles, and ghost cells. The same cells were visible in front of the

Fig. 7 (Loewenstein and Foster). Preretinal bands covered with lymphocytes and macrophages. Note the swollen ganglion cells.

membranes. The retina contained pigment clumps everywhere in the periphery.

The macular area was full of exudates (fig. 8). These were marked in the internuclear layer and pressed the fibers of Henle's layer apart. These fibers were very curved, and there were often only a few present between the eosin-red exudates (fig. 9).

The staining of the exudates was un-

Fig. 8 (Loewenstein and Foster). Cystic macular degeneration.

equal—some were stained a bright eosin red; others were paler. The larger exudates contained, as a rule, oval-shaped, empty spaces, corresponding to fatty enclaves. Since some of these fatty ovals still showed a dark purple nucleus and a granular mass, there was no doubt as to their origin from fat-phagocytizing (probably hexagonal) cells.

The macular exudates had expanded the retina to twice its normal thickness. Some of these exudates were directly beneath the internal-limiting membrane (see fig. 8). Where present, they had destroyed the regular scaffolding of the retina and altered

the order of the layers. Contraction of the deep exudates had even led to a folding of the posterior retinal surface.

The ganglion cells at the macula were particularly noteworthy, being sparse and of great size (fig. 10). The nuclei resembled those of the internal nuclear layers in size, but the protoplasm was three or four times as large as normal, stained with eosin and foamlike (fig. 10).

Slightly to the temporal side of the macula, the retina showed very few intact ganglion cells. The thickened eosin-red Mueller's fibers stood out sharply. In the outer molecular layer nearer the periphery, the layers became irregular. Glial fibers often accompanied by pigment cells traversed the whole retinal thickness in an oblique fashion. Midway between the disc and the ciliary body, heavy sub- and

intraretinal patches of pigment occupied the destroyed retina. A thick layer of pigmented masses and a criss-cross of glial fibers were left. The retina and choroid became fused long before the ora serrata was reached. The neuro-epithelium was absent for the most part, as in pigmentary retinal degeneration.

A flat plaque of nerve fibers and glial nuclei filled the concavity of the curved cribriform plate. Immediately behind the lamina cribrosa was an area of cavernous degeneration, absent from the posterior part of the optic nerve.

The endothelium of the arachnoid was markedly thickened, and the arachnoidal space was increased in size. A perfect corpus arenaeum powdered with lime was visible. This contained no iron.

Iron staining showed that there was no iron in the optic nerve and very little in the posterior part of the retina. Iron corpuscles were found nearer to the disc at the nasal side than at the temporal. The cystic area was practically iron free. While there were free, small, round iron corpuscles, the majority formed dark-blue intracellular patches. These exudates and the huge edematous ganglion cells were iron free.

The more peripheral the retina, the more degenerate it was, and the denser were the dark-blue patches. In addition, there were many light-blue lines and very fine granules (probably adsorption phenomena) at the surface of the individual cells.

The surface of the unstained exudates in the periphery (smaller than those in the macular area) showed a definite blue line.

Fig. 9 (Loewenstein and Foster). Cystic macular degeneration. Eosin-red exudate in the outer molecular layer with fatty corpuscular cells. Müller's fibers bend outward.

Except for isolated choroidal chromatophores and single hexagonal cells, there was little iron staining in the choroidal sections.

Even where the retina and choroid were indistinguishably fused, the blue retina showed diffuse siderotic changes; while in the pigmented choroid, single blue patches and single iron-filled cells of the chromatophore type only were visible.

RETINA AND CHOROID IN BULK

One's first impression on examining the inner side of the unstained retina in bulk was that of a dense fibrous tissue in

Fig. 10 (Loewenstein and Foster). Siderotic ganglion cells of the retina. Note vacuolation.

which both fine and coarse brownish-yellow pigment patches were visible. Heavy brown and black patches were isolated by fibrous tissue running concentrically round them (fig. 11). These pipelike spaces could be observed through the entire thickness of the retina. The most striking view was obtained by examination of the retina in bulk from the outer

maintained at the level of the outer retinal surface and its conglomerate hexagonal cells. Cross sections through peripheral retinal tissue showed these empty endothelial structures at the posterior retinal surface. A granular exudate in front of Bruch's membrane contained eosinophilic granules (fig. 13). It was vascularized and disintegrating, and corresponded to

Fig. 11 (Loewenstein and Foster). Retina in bulk. Unstained. Examined from the choroidal aspect. Note the dark, brownish retinal patches in all layers and the bands surrounded by pigment. The majority of the pigment patches are dome-shaped and are situated in empty spaces. The unstained bands may be identical with the fatty vascular network (posterior pannus, stained red with Sudan 3).

surface. Irregular, broad, stripelike bands divided the patchy, pigmented area. In the retina in bulk, stained with scarlet red, brownish patches outlined the course of these vessels which formed a regular network of shiny red bands. These were approximately equal in breadth, the largest being 45 to 50 μ m. wide (fig. 12a).

High-power magnification showed the bands to be lined with darker red patches parallel to their course. This network was located 50 μ m. below the retinal surface and was limited to the retinal periphery only. There was no evidence in any part of the network of a lumen or blood corpuscles. The distribution, particularly the branching, was reminiscent of a vascular system.

The major portion of this network re-

a posterior pannus. There was a certain similarity to the process of disciform macular degeneration in which capillaries from the choriocapillaris migrate through a break in Bruch's membrane.

The entire peripheral retinal tissue was a bright Prussian blue in which there were dark-blue patches corresponding to the dark-brown ones visible in the unstained retina in bulk (fig. 14). These blue patches were insulated by concentric glial bands. Many of the dark-blue patches contained a quantity of brownish elements (fig. 14) in which the iron molecule might be masked by a protein compound.

Similar structures could be found stained scarlet red in the choroid in bulk (fig. 15). Situated at the level of the hexagonal cells, they overlaid the regular ar-

rangement of the larger choroidal vessels. At some points their regular width was interrupted by an isthmuslike narrowing. The plane of these structures was about

fat granules; in others the processes were outlined by shining red fatty droplets.

When the choroid was stained for iron in bulk, the majority of the hexagonal

Fig. 12a (Loewenstein and Foster). Siderosis. Retina in bulk stained with scarlet red and examined from the outer surface ($\times 60$). The fatty vascular network, stained shining red with scarlet red is partly covered by degenerate hexagonal cells. The fatty cells and irregular branching of the vessels should be noted. The pigment of the hexagonal cells is partly brown and partly black, like Chinese ink.

30 to 35 μ beneath the chromatophore network in the suprachoroid. Here and there, however, conglomerations of hexagonal cells obscured the red network.

Many suprachoroidal chromatophores were filled with a mixture of pigment and

cells, whether intact or damaged, were iron-free. In the periphery, however, there were hexagonal cells, isolated or in groups, which contained iron granules. Some choroidal reticulum cells were filled with blue corpuscles.

Fig. 12b (Loewenstein and Foster). Retinal periphery ($\times 300$ H.E.). This section includes bands which may correspond to the fat-stained filaments in the retina in bulk. The red bands do not show up so well as in Figure 12a which was drawn through the microscope.

DISCUSSION

The symmetrical and equal distribution of the iron-containing corpuscles over the whole of Bowman's membrane, in spite of the lateral position of the foreign body, suggested that the distribution must have been via the blood and lymph streams and not by direct diffusion from the foreign body.

It was possible that the location of the

spherical bodies within Bowman's membrane was the expression of a reduced metabolism in the injured eye, similar to that associated with band-shaped corneal degeneration (Loewenstein, 1946).

Since the hypopyon contained only a moderate number of polymorphs and many macrophages and plasma cells, it was a chronic condition. Clinically such an hypopyon might be expected to be

Fig. 13 (Loewenstein and Foster). Granular mass located between Bruch's membrane and hexagonal cells may originate from the posterior pannus. (H.E. oil immersion). HC, hexagonal cells. GM, granular mass. BM, Bruch's membrane. ChC, choriocapillaris.

tough and firm. Its macroscopic appearance did, in fact, bear this out.

The scattered red corpuscles in the pectinate ligament were an unusual finding, as they showed no further signs of disintegration. Certainly there was nothing here reminiscent of the blockage of the ligamentum pectinatum which led to glaucoma in Erdmann's well-known experiments with electrolytic iron in the rabbit.

If the generally accepted view that iron is dissolved in the aqueous is correct, then it was extraordinary that the endothelium and Descemet's membrane should remain iron-free, although bathed for years in this solution. It is also difficult to explain why, when Descemet's membrane remained free from iron, Bowman's membrane should store it. *A priori*, one would expect the contrary.

It is possible that the calcium granules in Bowman's membrane were the sequel of chronic uveitis and that this might provide a nidus for the absorption of iron.

The plasmocellular iris infiltration was obviously a chronic change and, as suggested frequently in earlier papers, was reminiscent of an infectious granuloma (syphilis, for instance). The iris infiltra-

tion was unrelated to the site of the foreign body, as the plasma-cell infiltration, although patchy, was equally distributed.

The large mononuclear cells in the vitreous resembled those found in sympathetic ophthalmia. Since the majority of them were iron-free, they may have been an expression of longstanding irritation only.

Fig. 15 (Loewenstein and Foster). Choroid in bulk stained by scarlet red. Examined from retinal aspect ($\times 150$). The network of red-dish bands is about 8 to 12 μ broad.

In our case, there were wide areas over which the lens capsule had split off. This split glassy membrane was either loose or, where attached, arose at a sharp angle from the lens capsule. This splitting was in no sense radiational, as in fireworkers cataract, and was probably due to the toxic process. It is possible, in its etiology, it could be compared to senile exfoliation of the lens capsule, a condition whose pathology has not yet been completely investigated, and which may also be due both to failure of the intraocular metabolism and to toxic products.

The split was too extensive and the lamella too thick to be identified with Berger's zonular lamella. It is not impossible that there may be an unrecorded stratification in both the anterior and posterior capsules of the lens which would provide an anatomic basis for the breakaway of the anterior lamella, both in this case and in cases of fireworkers cataract.

The center of the shrunken lens contained a dark-purple mass, which might have been calcium phosphate, as hydrochloric acid dissolves it but does not evolve any bubbles.

The optic nerve and the posterior part of the retina and choroid were practically iron-free. The entire retinal periphery, not merely the peripheral retina around the foreign body, contained absorbed iron particles. The change was, therefore, independent of the site of the foreign body.

It is significant that there was no evidence of iron in the cystically degenerated macular area. We must conclude, therefore, that the macular disease was an indirect sequel of the intraocular foreign body and might have been due to the cyclitis present.

The swelling and degeneration of the macular ganglion cells was secondary, as was the overall reduction of the number of ganglion cells in the area where no iron was detectable.

The destruction of the peripheral retina would appear to have been a direct toxic effect; the damage to the choroid secondary.

The exaggeration of the glial lattice could be explained as an attempt at a kind of scar production, as in atrophies of nervous tissue. Glial growth predominated, as in retinitis pigmentosa, and was associated with pigmentary changes due to the migration of hexagonal cells along the glial bands into the shrunken retina. Most of the pigment was found in the deeper layers.

Another interesting feature was the band system found on the outer retinal surface. If these structures were of vascular origin, they might have originated in the choriocapillaris and broken through the lamina of Bruch. No histologic proof of this assumption was available.

Although reminiscent of vessels in some ways, there was, on the other hand, no evidence whatever of lumen in their bandlike cross section, nor did vessels exist either at this depth or in this peripheral part of the retina.

Since a great many hexagonal cells were destroyed, this layer adhered in part to the retina and in part to the choroid, as has been described. Our final assumption was that this band system was a posterior pannus. The positive scarlet reaction manifested a fatty degeneration of the wall in the whole system.

Vascularization between Bruch's membrane and the hexagonal layer in disciform macular degeneration has been recorded by Verhoeff and Grossman (1937) and Terry (1938). According to Reichling (1937, 1938) this condition may also occur in normal senile eyes. Loewenstein's investigations have confirmed both findings.

It is clear that during the 22 years the metallic splinter was imbedded in the eye,

parts of the iron foreign body were dissolved by the intraocular fluid, and certain of the eye tissues were saturated with iron. According to d'Amico (1925) the iron and tissue proteins combine and coagulate in an irreversible chemical reaction. We can, therefore, assume that any tissue found at biopsy to be free of iron has never in fact contained it. There are many reasons for believing that the vehicle of the iron transfer is the intraocular fluid and this reasoning is in fact generally accepted by all investigators.

The localization of iron in tissues by chemical methods enables us to use it as a "tracer" substance and a guide to ocular metabolism. For instance, the freedom of Descemet's membrane and the corneal lamellas from iron salts leads us to conclude that the endothelium was alive and impermeable to the ionized iron in the aqueous.

Further, if it is conceded that the vitreous contains iron salts from secondary siderosis, their absence from the macular area and optic nerve is surprising. From our observations, we might deduce that currents in the vitreous are equatorial and not in the antero-posterior direction, the metabolism of the posterior pole being a function of the choroid, slightly assisted by the retinal vascular system.

The usual reaction of the iris to iron is of a chronic granulomatous type, but evidence that acute, purulent inflammation (polymorphs) also occurred after 20 years of the presence of the foreign body is noteworthy.

Imbibition by the zonular fibers destroys their contractility; they elongate and finally rupture. The specific gravity of the lens then causes it to sink downward. The capsulo-epithelium degenerates, and the lens capsule splits as in the exfoliation of fireworkers cataract. The lens fibers degenerate and calcify.

The macular area degenerates cystically

(Haab, 1888). Fatty corpuscular cells are frequent around the eosin-red exudates in the outer molecular layers. It is our belief that these iron-free changes at the posterior pole of the eye were an indirect sequela of siderosis and were due to a chronic cyclitic process. The poor central vision sometimes found in cases of mild iridocyclitis may quite frequently be attributable to macular changes of this type.

The retinal periphery was both degenerate and saturated with iron. Pigmentary changes were marked, the migrating hexagonal cells being full of iron corpuscles. This last finding was a further confirmation of the phagocytic capacity of the mobile pigmented epithelial cells. A granular substance with minute eosinophil specks was situated between Bruch's membrane and the retina. The retinal changes corresponded to a regressive process—comparable to an abiotrophy. In both processes: (1) The location of the main changes was predominantly peripheral. (2) The nuclear layers were reduced. (3) The glial scaffolding was increased and associated with a tentaclelike migration of hexagonal cells through all the layers of the retina. (4) In both processes, where visual function was preserved, twilight vision was the first to fail.

The (fatty) degenerative, posterior pannus may be yet another expression of a dystrophic process. It is noteworthy that, up to now, changes of the last type have been found in disciform macular dystrophy and in senile retinal changes exclusively.

SUMMARY

Examination of an eye which had retained an intraocular iron foreign body for 22 years revealed the following points of interest:

1. The corneal epithelium, corneal lamellas, Descemet's membrane, and endothelium were practically iron free, while

Bowman's membrane was packed with particulate masses of spherical bodies containing iron.

2. The iron-saturated zonular fibers had ruptured, and the lens was shrunk, deformed, and freely movable in the vitreous. The lens capsule was split, as in fireworkers cataract or in senile and glaucomatous capsular exfoliation, but was iron free. The capsular epithelium was degenerate and contained iron.

3. A cystic degeneration of the macula was iron free but showed eosin-stained exudates and fatty corpuscular cells. Macular ganglion cells were swollen and fading.

4. The retinal periphery was heavily impregnated with iron and degenerate. Glial growth predominated.

5. The choroid was far less impaired.

6. The peripheral hexagonal cells were degenerate, packed with iron, and located for the most part along broad glial bands in the retina.

7. There was a granular substance between the choroid and retina with a remarkable, probably vascular, network, a highly developed posterior degenerative pannus, the vessel walls of which were completely infiltrated with fat.

ACCOMMODATIVE ASTIGMATISM*

JAMES MILES O'BRIEN, M.D., AND ROBERT E. BANNON, B.S.
Hanover, New Hampshire

It has frequently been observed that a difference in the amount and/or axis of astigmatism occurs during accommodation. Those who have carefully measured the amount of astigmatism during accommodation have found an increase necessary in the amount of cylindrical correction at near. However, a review of the literature reveals but few systematic investigations of this phenomenon. During the course of routine refractions here in the Clinic, our interest in this change was aroused. Those patients who have complained of discomfort during reading or at near were investigated in order to ascertain what part this near astigmatism played in their symptoms. We have attempted, therefore, to amplify and, if possible, to offer a more systematic and complete approach to this problem. The medical background for this change has been reviewed and a formula sufficiently accurate for our work is offered. The importance of these differences to the clinical ophthalmologist will be evident when considering the adequate correction of large cylindrical errors especially in young people. The near visual distance referred to in this paper is 16 inches and the distance vision is 20 feet, and any references to the near or distance vision will be to these distances only.

In explanation of these differences, that is, changes in the amount of astigmatism during accommodation, the following factors have been offered:

1. Asymmetrical or sectional changes of the crystalline lens during accommodation.

2. A change in the optical effectivity of

the spectacle lens at near due to accommodation.

3. Changes in the vertical meridian (cyclotorsion) of the eye during convergence and depression with resulting changes in the axes of astigmatism.

4. Changes in the corneal radii following convergence and depression of the eyes.

5. Changes in the shape and position of the crystalline lens itself during accommodation.

The idea that an asymmetrical contraction of the ciliary muscle could cause astigmatism was suggested by Dobrowolsky¹ in 1868. This might easily follow since lenticular astigmatism could readily be the cause of the differences found between subjective astigmatism and keratometric readings. In order to ascertain the existence of meridional lenticular accommodation, Hess² performed the following experiment. Two fine, white, cotton threads were used as test objects, these being mounted on separate supports and so arranged that each could be moved to and from the eye along the visual axis. The threads were placed at right angles to each other, these axes corresponding to the principal axes of the astigmatism. Each was now set at that distance at which the thread would be sharply defined in accordance with the previously measured astigmatism. If one thread were moved nearer the eye, an attempt to accommodate in this meridian would occur. Whether the other line remained clear or appeared blurred would be evidence for or against the existence of lenticular accommodation. Hess observed 23 cases, and in his series the astigmatic accommodation found was only of the order of

* From the Dartmouth Eye Institute.

0.1 D. Some of these changes might have been due to a rapid fluctuation in the total accommodation corresponding to the interval of Sturm.

This subject has been thoroughly reviewed by Erggelet,³ who coined the term near-astigmatism (*nahastigmatismus*). Erggelet was not of the opinion that asymmetrical lenticular changes were the cause of the increase in astigmatism during accommodation.

A few authors have written of changes observed in testing astigmatic subjects at 20 feet and 16 inches, the conclusion being drawn that these changes were due to meridional lenticular astigmatism. Lancaster⁴ reported a case, in 1916, of astigmatic accommodation in a patient following an attack of food poisoning in which the central nervous system become involved. The astigmatism varied in one eye from +0.75D. cyl.ax. 20° to +2.75D. cyl. ax. 80° through a six-months period. Under cycloplegic +0.25D. cyl.ax. 90° was measured. Lancaster concluded: "... It was natural to surmise that the change was due to a change in the action of the ciliary muscle. As the nuclear cells recovered from the damage by the toxin, some cells would recover better than others, and so the part of the ciliary muscle under their control recover tone better than the other parts; from this would result an unequal tension on the suspensory ligament and a consequent unequal curvature of the anterior surface of the lens."

Sheard⁵ also found astigmatic changes of from $\frac{1}{2}$ to $\frac{3}{4}$ D. at short-fixation distance, and he concluded that the possibility of accommodative astigmatism does exist.

In a recent paper by Hughes,⁶ eight cases of change in axis of astigmatism with accommodation were reported. However, only the fifth case presented can actually be said to give evidence of lenticular astigmatic accommodation. In this

case, a rupture of some of the zonular fibers was observable. Four of the remaining seven cases were presbyopic which eliminates the accommodation factor, and in three cases, corneal or lenticular pathologic conditions were noted. Sugar⁷ reported a study of 70 cases and observed changes in axis of the astigmatism at near, but apparently he made no attempt to determine the changes in *amount* that should occur in near vision. In both Hughes' and Sugar's papers, a change in the axis of astigmatism at near was noted but the increase in astigmatism at near when accommodation occurs was not considered.

Differences in the axis of astigmatism at near might be explained by a change in the cyclotorsional position of the eyes as they accommodate and turn downward. Because of the tendency for a cyclotorsional movement of the eyes to be associated with convergence, a regular shift of axis might be expected. However, generally this change is small and is ordinarily below the precision with which the axes can be determined.⁸ Large cyclophorias may occur with convergence in some individuals which would undoubtedly affect the axis of the astigmatic correction.

Two points should be remembered when dealing with astigmatism at the near point. First, there is a demonstrable change in the optical effectivity of the cylinder at near for an accommodating eye. Second, the astigmatism at near will be different with different methods of testing; that is, the use of different types of targets, such as letters, charts, and so forth.

EFFECTIVITY OF A CYLINDRICAL LENS FOR NEAR VISION

When the eye changes its fixation from a distant object to one at near, and accommodation occurs at the same time, it can be shown that the cylindrical effectivity of the lens correcting the astigmatism also changes. Percival⁹ notes: "After

correcting a high degree of astigmatism and obtaining a visual acuteness of 6/6 . . . I have often been disappointed with the result I obtained when testing the patient's near vision. . . . I determined to see if the effective value of the cylinder was altered when used for near work. To my surprise and delight I found that this was so, and my difficulty was thereby explained." The astigmatism of the accommodated eye, corrected for distance, becomes slightly undercorrected, the effectivity of the correction less. This effect was called "near astigmatism" (*nahastigmatismus*) by Erggelet to designate the apparent increase in the astigmatism that occurs when the eye wearing a correcting astigmatic spectacle accommodates for near visual distances. Therefore, a subject with an astigmatism of high degree can be fully corrected for 20 feet, but when accommodating at 16 inches, the effect of the cylindrical lens is decreased, and conversely the subject's astigmatism will appear increased.

A sufficiently accurate formula from which the required near cylinder can be computed, when the strength of the distance cylinder is known, is:

$$C_n = C_d [1 + 2h(\frac{1}{p} - A)]^*$$

where C_n and C_d are the astigmatic correction for near and distant vision; p is the near distance (in meters) from the lens, h is the distance of the lens from the eye and A is the spherical addition ("add") to the lens for near vision. In presbyopia an adequate near "add" must be included in the correcting lens. In this

case, then, $A = \frac{1}{p}$ and thus the effective

tivity of the near cylinder is equal to the distance cylinder. When the eye fully accommodates in looking from 20 feet to 16 inches, no "add" is needed and consequently $A = 0$, and C_n will be different from C_d . For a 1.00 D. correcting lens at 15 mm. from the eye and using a reading distance of say 30 cm., C_n will equal 1.10 C_d or the increase in the near cylinder will be in the order of 10 percent as compared to the distance cylinder.

Other sources of difference not included in the above formula may occur because of the following: In calculating the near astigmatism there will be a difference depending upon whether the more or less hyperopic meridian is taken as the reference for the accommodative change. The sphere used in sphero-cylinder combination may also, especially if high, affect the near astigmatism correction. The physical dimensions of the correcting lens used, especially thickness, will have a small influence. All these factors, however, introduce differences of the second order only, and can be neglected. We can thus see that in dealing with cylinders of large order, as Percival has noted, maximum visual acuity may not be obtained unless this change in near astigmatism is accounted for.

THE PRESENT INVESTIGATION

The essential contribution in the study reported here lies in the fact that three different methods of measuring the astigmatic error for both distant and near vision were used. Not only were changes in the amount of astigmatism at near measured, but also changes in the direction of the change of the axis at near were noted. The first method was the Lancaster-Regan astigmatic chart¹⁰ and dial. The second was the Jackson cross-cylinder test in which an attempt was made to maintain the strength of the

* We are indebted to Kenneth N. Ogle, Professor of Research in Physiological Optics, Dartmouth Eye Institute, for the derivation of this formula.

cross cylinder in keeping with the strength of the cylinder under estimation. The third was the method of stigmatoscopy which in our opinion offers the most accurate means of determining the amount and the axis of astigmatism at our disposal.

It was considered important that the

keep the posterior focal line of the interval of Sturm preretinal at all times. The effective fogging sphere was found by standard retinoscopic technique. For the near visual distance of 16 inches, reduced photographic reproductions of the Lancaster-Regan chart and dial as designed by Bannon¹¹ were employed. The chart

Figs. 1A and 1B (O'Brien and Bannon). For the near visual distance of 16 inches, reproductions of the Lancaster-Regan chart and dial were employed. These were attached to the opposite sides of a double sheet of heavy white cardboard. 1A, Near vision astigmatic chart. 1B, Near vision adjustable astigmatic dial. The dial was attached to the sheet of cardboard in such a way that it could be rotated by means of a handle through 90°.

technique employed in the near-vision tests should be as similar to those used for distant vision as possible. The cross-cylinder test on letters and the stigmatoscopy test are easily adapted for near-point estimation and the technique in each instance is substantially the same as that used for distance testing. However, in the case of the astigmatic chart and dial, there were none available for near-point use, and this resulted in our devising a near-point astigmatic chart and dial.

With the Lancaster-Regan astigmatic chart and dial, the system of adequate fogging together with the use of negative cylinders was followed. It was our aim to

and the dial were attached to the opposite sides of a double sheet of heavy white cardboard. The dial was attached in such a way that it could be rotated by means of a handle through 90°, in the same manner as could the large Lancaster-Regan dial (figs. 1A and 1B). This adaptation of the chart and the dial for use at near vision was found simple and yet effective in use. The dynamic cross-cylinder test¹² gives an indication of the amount of plus sphere necessary to place the conjugate foci in front of the retina. On the average, it was found necessary to add +0.50D. sph. to the distance correction in nonpresbyopic cases so that the patient would be properly

fogged for the near-point astigmatic test. The same routine of fogging together with the use of negative cylinders was followed. Sufficient positive trial-case spheres were again used to keep the astigmatic foci of Sturm's interval anterior to the retina. The routine differed actually in no manner from that employed at 20 feet.

In the cross cylinder test, we followed the technique as outlined by Jackson.¹³ This method was used for both the 16-inches and the 20-foot tests. In dealing with high astigmatic errors, the stronger cross cylinders were used and vice versa when the errors were small. By using the cross cylinder of powers comparable to the astigmatism, higher precision will result.

The method of stigmatoscopy is based upon the ability of the eye to discriminate, with precision, the change in blurredness of the retinal image of a point source of light. The instrument¹⁴ is essentially a haploscope in which the mirrors are half-silvered. This permits binocular fixation and fusion of a suitable target before the eyes, and at the same time permits point light sources supported on the arms, to be seen by reflection, and appear superimposed upon the target. Each eye sees a different point light source. These sources are mounted on riders which can be moved along the haploscope arms, and are maintained along the fixation lines of the two eyes. As the distance of one of the point light sources is changed, its blurredness will appear to change. The patient is directed to turn a suitable knob (which in turn moves the source along the arm) until the light appears smallest and nearest. At this position the source is conjugate to the retina, and the distance from the eye in diopters is a measure of the refractive condition of the eye. In an astigmatic eye the light source can be focused for one and then the other of the

Sturm lines. The difference in distances (in diopters) from the eye is the measure of the astigmatism. Visual acuity tests are used in conjunction with the test to determine the final spherical correction. Repeated settings permit unusual precision.

We feel that by the above three methods we have given a more careful study to the problem than has heretofore been available. The comparison of the three methods gives a good cross-sectional view of the refractive problem, not only with respect to the astigmatism but also the spherical error.

RESULTS

The data will be presented with respect to differences in the amount of astigmatism at near and differences in axis at near. The data are from 25 cases, spread evenly through cylinder ranges of 0.50D. to 5.00D. The stigmatoscopy data have been rounded off to the nearest 0.25D. In obtaining the change in the amount of astigmatism at near, 0.25D. was used as the standard, and no attempt was made to estimate changes of smaller degree. With respect to the change in axis, changes of 2 degrees represented the general amount of shift that could be accurately estimated.

A. DIFFERENCES IN THE AMOUNT OF ASTIGMATISM

An inspection of the table shows that there is on the average a small increase in the astigmatism at near, an increase that is consistent for all three tests. Only in one case was there a decrease at near. The average quantitative increase is shown in the scatter diagram in Figure 2, where the data are for the astigmatic chart and dial method. Clearly the points representing the measurements cluster about a line that has a slope about 10 percent higher than if no change in astigmatism

had been found. Thus on the average the astigmatism at near is measured 9 percent to 10 percent greater than is measured at distant vision. A comparison of the three tests as tabulated with respect to the increase in cylindrical power necessary to correct the astigmatic error at near is shown in Table 1.

Fig. 2 (O'Brien and Bannon). Scatter diagram showing change in astigmatism at near vision.

An increase in the astigmatism at near of about 9 percent should be expected in those cases where there is adequate accommodation (table 2).

B. DIFFERENCES IN AXES OF ASTIGMATISM

In studying the change in axis of the astigmatism from distance to near vision,

4.00 — up D.	2.3°	1.0°	2.4°

different strengths of the cylinder correction. Greater differences are found for the weaker cylinders, but of a magnitude which is believed greater than the variations that would occur in the precision of measurement.

In Table 4 are the tabulated results on the direction of these changes in axis. The significance of the difference in direction of these changes may be better appreciated if one considers that the stigmatoscopy

test is binocular; whereas, the chart and dial tests were monocular. One can see from Table 4 that there is a tendency for the superior pole of the vertical axis of the eye to rotate outward when tested binocularly as with the stigmatoscopy. Also it can be noted that, in testing mon-

TABLE 4
DIRECTION OF AXIS CHANGES AT NEAR
READING DISTANCE (16 INCHES)

Outward rotation of vertical axis	14	13	7
No change in axis	2	3	4

ocularly, this tendency toward outward rotation of the upper pole of the eye is less marked. Whereas, the number of eyes examined in this series is not considered significant enough to warrant a definite conclusion, it can be seen that relation of depression and convergence and cyclotorsion of the eyes when accommodating for near reading distances is most important.

Many more eyes should be used in an experiment of this type, for with the number of variables present, a greater number of cases in each category are really necessary before a fully satisfactory statistical study can be made. However, these data are significant and warrant their being summarized at this time.

SUMMARY

The astigmatism was measured on 50 eyes for distance and near vision by three techniques: (1) the Lancaster-Regan chart and dial, (2) the cross-cylinder, and (3) the stigmatoscopy methods. A consistent increase in astigmatism of from

8 percent to 10 percent was measured for near vision by all three methods. This increase was in the direction and approximate amount to be expected due to the loss in effectivity of cylinders prescribed for distance vision when used for near vision, before a fully accommodating eye. For astigmatic errors of the lower powers this factor is negligible, but for higher powers it should not be neglected.

Change in axes of the astigmatism was also found but there was no trend in this change consistent with changes in cyclotorsional positions of the eyes with convergence or lowering of the eyes.

CONCLUSION

If we have stimulated the interest of the practitioner in looking for these changes, the purpose of this paper has been achieved. Suffice it to say that the facts exist, but by and large they have been overlooked or ignored by most practitioners. Their importance is evident when one considers the problem of large astigmatic errors in young people. We have attempted to demonstrate that the distance refraction cannot in itself be considered accurate at near when astigmatism is involved to any significant degree. The difference between the rote method of refraction and that of the skillful refractionist's will be reflected in the results obtained. Changes in amount and/or axis of astigmatism at the near point should be looked for, and with a full knowledge of the results to be sought and the methods applied, one more weapon in the armamentarium of the competent refractionist is available.

The authors wish to acknowledge, with gratitude, the advice and inspiration received from Dr. Walter B. Lancaster.

INVOLVEMENT OF THE ORBIT IN CHRONIC INFLAMMATION OF THE FRONTAL SINUS*

M. C. BENFORD, M.D., AND HANS BRUNNER, M.D.

Chicago

It is a well-established fact that chronic diseases of the frontal (and ethmoid) sinus may involve the orbit. Among these diseases, the mucocèles and pyocèles are most frequent, causing pseudotumors in the inner and superior angle of the orbit. In fact, the tentative diagnosis of mucocèle is almost immediately made when there is a tumor covered by normal skin in the inner and superior angle of the orbit, above the internal palpebral ligament. It is of minor importance whether or not there is a displacement of the eyeball and whether palpation of the tumor yields fluctuation.

The purpose of this paper is to demonstrate: (1) that tumors in the inner and superior angle of the orbit are not always caused by mucocèles of the frontal and ethmoid sinuses; and (2) that extension of chronic inflammation of the frontal sinus does not always occur into the inner and superior angle of the orbit.

Tumor formation in the inner and superior angle of the orbit may occasionally indicate a pathologic condition in the orbit without involvement of the paranasal sinuses. In this respect, the so-called pseudotumors of Birch-Hirschfeld¹⁻⁹ are of great interest. The term denotes a finding which usually shows proptosis, limitation of eye movements, increase in bulk of the orbital tissue, and possible swelling of the lids. The onset is slow, and the usual signs of inflammation are absent. The etiology of pseudotumors of

the orbit is not known, although in several cases tuberculosis, syphilis, or focal infections were considered responsible. Pseudotumors are not frequent; nevertheless, the clinical evaluation of these granulomas is important from a practical standpoint, since there are instances reported in which an exenteration of the orbit was performed under the pretext of removing a malignant tumor.

Although in the advanced stage pseudotumors may give the impression of malignant orbital tumors, in the early stage they might be considered as being rhinogenic in origin. As pointed out by Meller^{5,6} pseudotumors are frequently noticed first at the superior, or superior and mesial, margin of the orbital opening, at a site which is likewise occupied by mucocèles or abscesses originating in the paranasal sinuses.

CASE REPORTS

The following case is of interest because it did not present the eye symptoms which are supposed to be typical in instances of pseudotumors.

CASE 1

History. J. F., a man aged 32 years, noticed about eight years ago a swelling the size of a pea in the inner angle of the left eye. This grew slowly to the size of a cherry stone. He was never injured at that site. Three years ago, a surgeon incised the swelling and removed part of it. Following the operation, the tumor became even larger than before. Eight months later, the tumor was again removed by another surgeon. After this operation, the eye was closed and swollen for five weeks. Four months after the

* From the Department of Ophthalmology and Otolaryngology, University of Illinois, College of Medicine.

second operation, the tumor again recurred. The patient did not complain of headache. Occasionally, there was a great amount of mucous discharge from the nose, and this was followed by a decrease of the swelling over the eye.

Examination. On examination, June 15, 1945, there was a swelling in the inner

Fig. 1 (Benford and Brunner). Note the scar in the inner angle of the left eye after removal of a pseudotumor.

angle of the left eye, located above the internal palpebral ligament and covered by normal skin. The swollen area extended over the bridge of the nose toward the glabella. In the skin, small surgical scars were noticed.

The tumor had a medium-soft consistency. The left palpebral fissure was narrower than the right. Eye movements were normal, and there was no exophthalmos. The right nostril was normal. On the left side, the agger nasi and the uncinat process were bulging. There was no secretion in the nose. X-ray films

showed a slight haziness of the right ethmoid, right-frontal and right-maxillary sinuses. The left frontal sinus was not developed. The left ethmoid was clear; the left maxillary sinus was slightly hazy. There were no signs of tuberculosis, lues, or leukemia. The tentative diagnosis of a mucocele of the left ethmoid was made. On July 5, 1945, an arcuate incision was made in the inner angle of the left eye under local anesthesia. In the supraorbital arch, a diffuse, soft swelling was found, the puncture of which did not reveal fluid. The periorbit was elevated down to the posterior lacrimal crest, and a communication to the nose was created through the frontal process of the maxilla.

A tumor the size of a date was found. This apparently had the insertion on the posterior lacrimal crista. The tumor penetrated the orbital septum and extended toward the glabella and to the center of the supraorbital arch. In the orbit, the tumor was located between the periorbit and the bone; at the forehead, between the skin and the thickened periosteum of the bone. Numerous branches of the anteriorethmoidal and supraorbital nerve passed through the tumor. These branches were severed, and the tumor was removed by blunt dissection. The hemorrhage was considerable. After removal of the tumor, a shallow groove was found in the frontal squama together with a thickening of the lacrimal bone. Uneventful recovery ensued. There was no recurrence during an observation period of nine months (fig. 1).

Microscopic Examination. The tumor consisted of connective tissue, striated muscle fibers, small blood vessels, and nerves. The connective tissue was firm. It did not show degeneration nor definite signs of inflammation. The nerves were normal, as were the walls of the small arteries. The small veins showed a peri-

vascular infiltration consisting of loosely arranged lymphocytes and plasma cells. Occasionally the cells were adjacent to only one wall of the vein, while the opposite wall did not show infiltration.

The muscular tissue occupied the greater part of the specimen. The muscle fibers were to a great extent entirely normal. There were, however, several lo-

form follicles and invade the muscle fibers, the remnants of which could be seen between the lymphocytes (fig. 3). There were no giant cells.

Comment. In this case, the erroneous diagnosis of a mucocoele was based upon a misleading history given by the patient. Since there was no exophthalmos or limitation of eye movement, it was scarcely

Fig. 2 (Benford and Brunner). Note the accumulation of lymphocytes between the muscle bundles and along the capillaries.

calized spots presenting different changes. The slightest change consisted of an edema of the muscle. At these sites, the muscle fibers might show a normal structure, or they might have lost their striation and be broken up into several pieces. Between the muscle fibers, there were usually a few scattered lymphocytes. At other sites, there was an accumulation of lymphocytes and plasma cells between the muscle fibers, usually surrounding a capillary (fig. 2). These accumulations of lymphocytes might reach such a size that they could be seen macroscopically. In such instances, the lymphocytes might

possible to make the correct diagnosis. The operation was hemorrhagic; nevertheless, the tumor was removed since it did not extend too far into the orbit and was fairly well encapsulated. Whether or not the cure is definite, cannot be stated because in these instances, recurrences in the same or in the other eye may occur after a period of several months. In the event of a recurrence, the appropriate treatment would be administration of iodine and arsensics, and eventual X-ray therapy, rather than surgical intervention.

According to Birch-Hirschfeld,³ the principal microscopic features of these

tumors are: (1) Accumulation of lymphatic tissue. (2) Proliferation of the intima and hyaline degeneration of the walls of the blood vessels. In the presented case, the changes in the blood vessels were absent, but the accumulation of

of animals. This concept likewise does not agree with the findings in the presented case, since the accumulation of the lymphatic tissue was found almost exclusively within the muscular tissue covering the supraorbital arch.

Fig. 3 (Benford and Brunner). Microscopic section showing two lymph follicles and lymphatic infiltration between the muscle fibers.

lymphatic tissue was marked and the formation of follicles was noted.

The pathogenesis of the lymphatic tissue is not clear. Several ophthalmologists believe that it derives from the small amount of lymphatic tissue which is found in the fornix conjunctivae and near the lacrimal gland under normal circumstances. This concept does not agree with the finding in the presented case since the tumor had no relation to the fornix or the lacrimal gland. Birch-Hirschfeld claims that the lymphatic tissue may originate from the lymphatic crevices which he has found in the orbits

In striated muscles, lymph vessels are found only on the outside, but they seldom extend into the muscle along the broad connective tissue septa, and are never found between the muscle fibers (Schaffer). For this reason, the lymphatic tissue did not originate from the lymph vessels of the muscle. The microscopic examination revealed that the lymphatic tissue apparently originated from the capillaries between the muscle fibers. Neither microscopic examination nor clinical observation gave any information concerning the etiology of the pseudotumor in the presented case.

Although the tumor of the orbit in Case 1 was erroneously considered to be of paranasal origin, inflammatory tumors of the orbit of definite paranasal origin were found in Cases 2 and 3. This finding is important because inflammatory tumors of the orbit arising from the paranasal sinuses are practically unknown, if one excepts the rare occurrence of tuberculosis of the ethmoid which extends into the orbit. This contrasts sharply to the incidence of acute inflammation of the orbit originating in the paranasal sinuses which accounts for about 60 percent of all cases.

CASE 2

Z. B., a white woman aged 21 years, was hit in the region of the mesial canthus of the left eye by a peach pit shot from a sling shot. Shortly after this accident occurred, 12 years ago, she injured her nose in the region of the left eye by bumping herself on a desk. Soon after these two injuries, she noticed a swelling in the region of the inner canthus of the left eye. This was accompanied by considerable pain in that area and in the eye, as well. Intermittently, the pain was so severe that her eyeball felt like it was going to burst. The pain continued, and the swelling advanced, involving the mesial angle of the eye (fig. 4). At times the eye swelled shut and became black. These attacks came on when she had a head cold or became nervous. Cold wind or night air would start the pain. Soon after, the swelling would increase and become discolored. As soon as the head cold subsided, the black color would rapidly disappear.

About five years before this examination, there was a yellowish discharge from the nose. This discharge continued and became worse when the patient had a cold.

Examination. At admission, June 8,

1944, a swelling was found at the inner angle of the left eye above the internal palpebral ligament and extending toward the bridge of the nose and the glabella (fig. 4). The swelling was covered by normal skin and had a doughy consistency. There was no defect of the

Fig. 4 (Benford and Brunner). Note the tumor in the inner angle of the left eye.

underlying bone. The left eye seemed to be slightly displaced downward. The left middle turbinate was slightly hyperplastic, but there was no other pathologic condition in the nose.

X-ray studies showed the following: Absence of the left frontal sinus; absence of a part of the mesial superior portion of the left orbit with some upward displacement of the margins of the defect and sclerosis of that area; clouding over the left ethmoidal, maxillary, and sphenoidal sinuses (fig. 5). Wassermann and Kahn tests were negative. It was not

possible to make a definite diagnosis. The tentative diagnosis pointed to either a chronic osteomyelitis of the left supra-orbital ridge or to a mucocele of the ethmoid.

Under general anesthesia, an arcuate incision was made in the inner angle of the left eye, and immediately a large mass of granulation tissue was exposed. The hemorrhage was formidable, and it was

Two days after the operation, there was a marked swelling of the skin over both upper lids and forehead, but there was no redness of skin. There was no pain and no fever. Nevertheless, the wound was partially opened, and 10,000 units of penicillin in 5-percent glucose were administered intravenously over a 10-hour period. The patient made an uneventful recovery, and 11 months later she felt fine,

Fig. 5 (Benford and Brunner). a. Chronic osteomyelitis of the left supraorbital ridge. b. Small frontal sinus on the left side.

extremely difficult to separate the thickened and granulating periosteum from the floor of the frontal sinus. The granulating periostitis extended deeply into the orbit along the superior and the mesial walls. The frontal bone was uneven, sclerotic, and anemic. There was no pus.

Since the condition of the patient did not permit the removal of the floor of the frontal sinus, the frontal process of the maxilla was removed, and the anterior ethmoid was curetted in order to perform a wide drainage of the periostitis into the nose. There was no involvement of the posterior ethmoid. The skin incision was partially closed.

had good appetite, and was gaining in weight. There was almost no headache, but the tumor in the inner angle of the left eye had not changed.

Comment. This was a typical case of primary, chronic osteomyelitis of the frontal bone following injuries to the bone. Usually an infection of this type causes a thickening and sclerosis of bone, eventual necrosis, formation of sequestra, and an infection of the frontal sinus. In the presented case, the disease ran over a period of 12 years, and the outstanding symptoms were severe headache, toxemia, and a tumor formation in the inner angle of the left eye.

The tumor consisted of granulations which were covered by a normal skin. The granulations were caused by a granulating periostitis (fig. 6) which extended deeply into the orbit. This is an occasional finding in syphilitic periostitis of the frontal bone. However in the presented case, the Wassermann and Kahn

for three reasons: (1) The patient had not given consent to that type of operation, since a definite diagnosis had not been made prior to surgery. (2) The operation would have resulted in a bad disfiguration of the face. (3) The simple exposure of the frontal sinus had caused such a formidable hemorrhage that

Fig. 6 (Benford and Brunner). Po, Periosteum; F.S., Frontal sinus; a. Tumor consisting of granulation tissue, due to a granulating periostitis; U.L., Upper lid; O. Eyeball.

tests were negative. This case proves, therefore, that common chronic osteomyelitis of the frontal sinus may occasionally cause inflammatory tumors of the orbit which consist of granulation tissue and are due to a granulating periostitis of the anterior and inferior sinus wall.

The excruciating pain which the patient was suffering, required surgery. The proper operation would have been the removal of the entire osteomyelitic area. This operation was not performed

a radical operation upon the thickened and sclerotic bone would have been fraught with hazards.

For these reasons, it was decided to create a decompression of the orbit into the nose. The frontal process of the maxilla and the anterior ethmoid were removed so that the granulations could bulge into the nose. The result of this decompression was satisfactory. The patient was almost completely relieved of headache, gained weight, and was in good spirits. Nevertheless, it is questionable

Fig. 7 (Benford and Brunner). 1. This picture indicates the findings prior to operation. Note the tumors in the outer angle of the right eye and in the inner angle of the left eye. 2. This shows the patient after the operation.

whether or not this result will be permanent.*

CASE 3

J. M., a man, aged 61 years, fell on his head from a horse 40 years before. Three years ago he noticed a bilateral growth above both eyes. An unsuccessful operation was performed. Polypi were removed from the nose on April 22, 1944. Bone was found within the polypi. This operation likewise had no influence upon the tumors above the eyes. There was an occasional headache.

Examination. On examination, October 19, 1945, a tumor, 1.5 x 2 cm. was found, covered by normal skin. It was located in the lateral part of the right upper lid (fig. 7). The tumor pushed the eye downward and narrowed the palpebral

fissure; it also raised the lateral part of the eyebrow.

On palpation, the tumor presented a fluctuating encapsulated mass which apparently protruded through a perforation in the floor of the right frontal sinus. The margins of the opening in the floor of the sinus were markedly thickened.

The right eye was normal except for a slight restriction of the movement upward. In the mesial portion of the left upper lid, there was an opening in the skin about the size of a penny. The margins of the opening were sharp, not granulating, and a tumor the size of a normal ovary emerged through the opening.

The tumor consisted of polypoid tissue, and a small amount of mucopus escaped between the polypi. When pressure was exerted upon the tumor on the right side, a great amount of pus escaped between the polypi on the left side. The

* The result was not permanent, since headache returned several months later.

left eye was displaced inferolaterally. The skin over the left tear sac was inflamed, but there was no dacryocystitis. The supraorbital ridge on the left side was uneven but intact. Conjunctiva and eye movements were normal on the left side. The right nostril was filled with polypi. The left nostril was large; the

frontal sinus was exposed and found to be normal except in the most lateral part where a narrow fistula was noticed. A sac filled with pus emerged through the fistula. The walls of the sac were firmly adherent to the periorbit and were a continuation of the mucosa of the frontal sinus. In other words, the tumor of the

Fig. 8 (Benford and Brunner). Po, Periosteum; F.S., Frontal sinus; b, Herniation of the frontal sinus mucosa, filled with pus; U.L., Upper lid; O, Eyeball.

inferior turbinate atrophic. There were two large polypi, both apparently originating in the ethmoid. The epipharynx was filled with mucopus, and the breath had a foul odor.

X-ray films showed an increased density over the left maxillary antrum, ethmoids, sphenoids, and frontal sinuses. On October 20th, the tumor in the right upper lid was exposed, the capsule incised, and 20 cc. of pus were aspirated. The pus contained hemolytic staphylococcus aureus.

An arched incision was then made below the right eyebrow. The floor of the

right upper lid was caused by a herniation of the mucosa of the frontal sinus which had escaped through a narrow fistula in the floor of the sinus (fig. 8).

Next, the floor of the sinus was removed. The entire sinus was filled with polypi which extended into the sac that emerged through the fistula. A part of the frontal process of the maxilla, including a part of the apertura piriformis, was found to be transformed into a sequestrum. The sequestrum was removed. This created a large opening into the nose. The anterior ethmoid was curetted.

The next step was to make an arched incision below the left upper eyebrow. There was a large perforation in the floor of the frontal sinus and in the lateral wall of the anterior ethmoid. Through this large perforation protruded polypi which were in direct connection with the polypi forming the tumor in the upper eyelid.

The left frontal sinus, which had a

the opening into the nose. After removal of the membrane, the right ethmoid was found to be filled with polypi and bony sequestra which were remnants of the bony septa between the ethmoid cells. The polypi were thoroughly removed, and the fistula in the left upper eyelid was closed. Uneventful recovery ensued.

Microscopic Examination. The sac on the right side (fig. 9) consisted of con-

Fig. 9 (Benford and Brunner). Section through the herniation of the frontal mucosa on the right side. a. Squamous epithelium; b. Blood vessels with perivascular infiltration; c. Opening of the sac toward the frontal sinus; d. Fibrin within the opening.

large temporal recess, was entirely filled with polypi that extended through a perforation in the interfrontal septum into the right frontal sinus. All polypi were removed. The posterior walls of both frontal sinuses were normal.

On the evening following the operation, the patient's temperature rose to 104°F. (rectally) due to a bronchitis. Penicillin was given, and the temperature fell gradually by lysis until it became normal on October 28th.

Since the right nostril was filled with polypi and bony sequestra were palpated within the polypi, an external ethmoid operation was performed under local anesthesia on November 24th. A thick connective-tissue membrane that had grown together with the periorbit had closed

nective tissue which was covered by an intact, somewhat thickened epithelium associated with papillary areas which were lined by respiratory epithelium. The latter zones were vascular and markedly infiltrated by round cells, while the former zones presented a moderate infiltration. The mass from the upper lid consisted of markedly edematous tissue associated with round-cell infiltration and with widely dilated blood vessels. The covering epithelium was markedly hyperplastic, thrown into irregular folds, and permeated by numerous polynuclear cells. Occasionally, there was respiratory epithelium. There was no evidence of malignancy. Within the polyoid tissue, atrophic bone trabeculae were found, apparently originating from the ethmoid

(fig. 10). The margins of the trabeculae were aplastic, and there was a loose connective tissue between them. There was no inflammation of the connective tissue.

Comment. This is a case of chronic, purulent infection of the frontal and

cranial complication. Rarely does the abscess in the orbit become encapsulated. In the presented case, there was an enormous amount of polypi within the sinus while the accumulation of pus was less conspicuous. The osseous wall was per-

Fig. 10 (Benford and Brunner). Section through the polypus in the left ethmoid. a. Hyperplastic squamous epithelium; b. Atrophic bone; c. Loose connective tissue; d. Edematous connective tissue.

ethmoid sinuses in which the infection has ruptured into the orbit. Cases of this type are by no means rare. However, in certain respects the presented case differs definitely from the usual type.

Commonly, an accumulation of pus is found in the sinus, and there is an osteitis, necrosis, and finally a fistula in the osseous wall. Through the fistula, pus escapes into the orbit causing an acute orbital infection which may subside spontaneously, or requires surgery, or eventually causes an intra-

forated on the left side, but it seemed as if this was caused primarily by pressure due to the polypi and not by an osteitis.

The following findings favor this concept. The patient gave no history of marked headache. If there had been an osteitis, he would have suffered from headache. The bone which was embedded in the nasal polypi was atrophic but did not show signs of inflammation. The margins of the skin fistula in the left upper lid were epithelialized, not granulating. No pus had escaped into the orbit, causing

an orbital inflammation; but polypi and sinus mucosa bulged into the orbit, causing pseudotumors of the orbit. The frontal sinus mucosa which bulged into the right orbit presented only a moderate degree of inflammation. This indicated that the absorption of the underlying bone was due to pressure rather than to infection.

Although absorption of bone due to pressure also occurs when mucoceles or pyoceles extend into the orbit, the tumor mass in the right orbit cannot, in this case, be considered a mucocele or pyocoele. In mucocele a large part of the osseous sinus wall—the size depending on the size of the mucocele—becomes atrophic, bulges into the orbit because of the pressure of the mucocele, and ultimately becomes absorbed. In the presented case, there was a narrow fistula in the floor of the frontal sinus, and the margins of the fistula consisted of thickened bone. Through the fistula, a comparatively large sac bulged into the orbit. The outside of the sac did not reveal any remnants of bone. For this reason, we considered that the finding in the right orbit was not a pyocoele, but a herniation of the frontal-sinus mucosa. Unless they are caused by

a malignancy of the paranasal sinuses, incidences of this type are rare. However, the clinical and microscopic examination did not reveal any signs of malignancy in this case; nor did the long duration of the disease favor the concept of malignancy.

CONCLUSIONS

1. Pseudotumors of the orbit (Birch-Hirschfeld) may occasionally occupy the inner and superior angle of the orbit, thus simulating a tumor of paranasal origin.

2. Inflammatory orbital tumors of rhinogenic origin do exist, but they are not as common as acute orbital infections of rhinogenic origin.

3. The inflammatory orbital tumors of rhinogenic origin arise from infections of the ethmoid and/or frontal sinus.

4. Inflammatory orbital tumors of rhinogenic origin may be caused by: (a) a granulating periostitis, (b) a herniation of the mucosa of the paranasal sinuses, (c) an invasion of the orbit by nasal polypi.

OBSERVATIONS ON 300 CONSECUTIVE CASES OF OCULAR WAR INJURIES*

JOHN G. BELLOWS, M.D.
Chicago

The subject of ocular war injuries is of great importance in military surgery, not only for scientific and humane reasons but also from an economic standpoint. Many of the soldiers with eye injuries become unfit for further military service, as well as for many civilian occupations. Moreover, they form an economic group which requires tremendous expenditures for their postwar care. In modern times each succeeding war has shown an increase in the number of ocular injuries in relation to the number of injuries to all other parts of the body. It must be remembered that the incidence of ocular injury is likely to be underestimated rather than overestimated because many of the cases are associated with fatal head wounds.

It is not surprising that the eyeball, although measuring but 1/375 of the body surface, should be so frequently injured, if one considers the great vulnerability of the eye to small particles. For example, a minute flying particle which would be stopped by clothing or be unnoticed if embedded in the skin may cause a severe injury when it penetrates the eyeball.

It is for this reason that eye injuries form a larger proportion of all types of severe injuries as the distance from the explosion increases. Blake¹ reports that ocular injuries form two percent of all injuries occurring at distances from 0 to 50 feet and 14 percent of all injuries at 150 to 200 feet.

In World War I the incidence of ocu-

lar casualties rose to eight percent of all injuries. The data on the number of eye casualties in World War II are not yet available, and estimates by various observers differ widely. Vail² states that they comprised about two percent of all injuries in the European Theater. Loewenstein³ early in World War II found that 12 percent of all injuries were to the eye. Cordes⁴ believes that the percentage may even rise as high as 15 to 17 percent. MacFee⁵ found that in 141 Air-Force combat casualties 12 percent were ocular injuries. Schench⁶ and others surveyed 3,019 casualties on a hospital ship and found that 451 or 15 percent suffered eye injuries. Wisner⁷ reports that ocular injuries were present in eight percent of all casualties brought aboard a hospital ship.

The frequency of ocular injuries varies with the type of warfare. During a rapid advance, because the entire body of the soldier is exposed, there are relatively few ocular injuries. Such was the case after the break-through in Normandy. The incidence of ocular injuries rises when the battle front becomes static because the soldiers must take to trenches and foxholes, where the body is protected while the head and eyes are exposed for observation or shooting. This occurred during the campaign on the Italian front.

Other important factors in the rising number of eye casualties in modern warfare are:

1. The increased range and explosive power of high caliber shells and grenades.
2. The use of land mines, which frequently produce bilateral ocular wounds.

*From the Department of Ophthalmology, Northwestern University Medical School.

3. The increased use of tank warfare, with the unavoidable exposure of the head and eyes of the tank commander.

It is the purpose of this report to record the findings of 300 consecutive cases of ocular casualties which were observed at a U. S. Army hospital designated as an Ophthalmic Surgical Center.

The modern soldier may receive injury not only in combat but also as the result of noncombat duties (see table 1). Injuries to the eyes caused by flying chips of steel, glass, rock, or sharp implements, similar to those observed in civilian life and industrial practice, require no further mention here. Since ocular injuries caused by explosives during demonstrations or through careless handling are similar to those occurring in combat, they are included.

Shell fragments caused 163 cases, or 54 percent, while bullets produced 34 cases of ocular injury, or 11 percent (see table 1). Rohrschneider,⁸ in his report on the eye casualties in the German army, submitted figures surprisingly similar to mine, namely, 56 percent of the injuries were caused by shells and 11 percent by bullets.

Ocular war wounds may be classified as follows (see table 2):

TABLE 1

WAR IMPLEMENTS PRODUCING OCULAR INJURIES
AND PROPORTION OF EYE INJURIES TO
OTHER INJURIES

Cause of Injury	Injuries to Eyes Only*	Injuries to Eyes, Body, and/or Extremities	Total

BLAST INJURY TO THE EYE

Injury to the eye by shells, grenades, or mines is usually due to the effect of fragmentation; however, severe ocular trauma can also be caused by an explosive force. A simple ocular blast injury shows no trace of a foreign body. Frequently, however, dust, débris, and other particles are driven into the eye by the blast. In such cases, it is difficult or impossible to distinguish between the damage caused by the blast and that caused by the flying particles.

Campbell⁹ describes the blast due to bomb explosion as a sudden compression and expansion of the atmosphere. The eye and ear are particularly vulnerable because of the exposed position of the eye and the physiologic adaptability of the ear to receive pressure. Bonnet¹⁰ believes that the injury is produced by the shock of the advancing air wave generated by the explosion. Young¹¹ explains the damage following blast injuries as due to the sudden increased pressure, which may rise as high as several atmospheres. This pressure is applied to all the surfaces of the body. There is no unanimity of opinion regarding the incidence of blast injuries to the eye. Zuckerman¹² doubts that blasts are a common cause of ocular injuries and gives as a reason that if an individual were close enough to an explosion to receive ocular damage from the blast, his injuries would be fatal.

Fig. 1 (Bellows). Bilateral iridodialysis caused by an explosive blast.

Further, he has found that most individuals exposed to high blast pressure fail to demonstrate ocular injuries.

On the other hand, Wiener¹³ writes that rupture of the choroid without even a bruise of the external eye or lids results not uncommonly from explosive forces. He describes a case of aneurism of the lateral sinus following an explosion. Vail² also found that blast is a frequent cause of ocular injuries (fig. 1).

These changes have been observed in blast injuries: Chemosis; hemorrhage leading to proptosis and optic atrophy; intraocular hemorrhage resulting from iridodialysis or the rupture of a retinal vessel; choroidal rupture and retinal hemorrhage, and acute iridocyclitis with secondary glaucoma.

In the 300 cases in this report there

were 13 soldiers who suffered from severe ocular trauma due to nearby explosions. Only those patients exposed to a blast, in whom there were no apparent injuries by impact or penetration of a foreign body and yet who showed serious ocular pathologic conditions, were con-

sidered as blast injuries. Table 3 shows the chief ocular lesions and resulting visual acuity following blast injuries to the eye.

THERMAL INJURIES

There were three soldiers in this group who suffered from burns. Gasoline fire caused the burns of two of the men. The third was injured when his plane crashed and caught fire.

The lids were markedly affected and corneal opacities were present in all three (fig. 2).

INDIRECT OCULAR WAR INJURIES

This type of injury generally results from the enormous kinetic energy of a rapidly moving missile striking tissues in the vicinity of the eyeball. Powerful concussion waves produced by the projectile cause severe ocular lesions. Thus, a rapidly moving projectile passing through the orbit without striking the globe may produce a rupture of the eyeball opposite the point of impact. For example, a projectile penetrating the retrobulbar region may give rise to a rupture of the cornea, and one passing lateral to the globe may

Fig. 3 (Bellows). Bullet in retrobulbar region caused choroidal rupture with atrophic chorioretinitis. Enophthalmos is present.

cause rupture near the opposite equator. Kaminskaya¹⁴ finds that indirect ocular injuries occur most commonly following injuries of the lower outer orbital margin and the zygomatic arch. Ocular lesions resulting from injuries of the inner orbital wall and nose are less frequent.

The lesions resulting from this form of indirect injury involve the posterior segment more often than the anterior. The explanation for this occurrence, according to Lagrange,¹⁵ is that the macular area is the most fragile and -vulnerable region and that the concussion waves toss the eyeball about within the orbit, causing traction on the optic nerve to produce posterior lesions (fig. 3).

Symptoms naturally vary with the extent, location, and nature of the lesions. They may appear immediately or may not become evident for days or even months. Intraocular hemorrhages are frequently present although peripapillary and macular hemorrhages are more common. Kaminskaya¹⁴ believes that the injury which produces subluxation of the lens in the anterior segment causes, in the posterior segment, a reverse wave which separates the vitreous and the retina. This produces a vacuum which, in the presence of the alterations in the vessels (spasm followed by dilatation and increased permeability), leads to hemorrhages. Edema of the disc and retina with choroidal rupture are frequently encountered (fig. 4). Lister¹⁶ terms "grossly concussed fundus" a lesion which in the early stages is characterized by hemorrhagic clouds, white particles which represent patches of coagulation necrosis from rupture of choroidal and retinal vessels. These patches change gradually into fibrous tissue. Later, secondary lesions appear, consisting chiefly of atrophic and proliferating chorioretinitis.

Purtscher¹⁷ was the first to call attention to an interesting form of indirect

ocular injury which is now known as "traumatic liporrhagic retinalis." Cases have been reported resulting from fracture of the vertebrae or compression injuries to the thorax and abdomen. Purtscher¹⁷ explains the pathogenesis of the retinal changes as follows: Compression of the longitudinal axis of the spine due

Fig. 4 (Bellows). Shell missile injury to face producing ipsilateral choroidal rupture.

to head injury increases the cranial pressure; the pressure is transmitted along the intervaginal space and then into the nerve head; this results in an extravasation of fluid into the retinal spaces. The more recent authors attribute the changes to fat emboli. Friedenwald,¹⁸ Urbanek,¹⁹ Loewenstein,²⁰ Verhoeff,²¹ and Spaeth²² think the retinal changes are due to a generalized diffusion of fat droplets in the fundus. Therefore, the term "traumatic liporrhagic retinalis" has been applied to this condition. The usual ophthalmoscopic findings consist of hemorrhages, exudate, and edema with destruction of the arteries and dilation of the veins.

Finally, ocular alterations occur indi-

Fig. 5 (Bellows). Horner's syndrome following a wound in the supraclavicular region.

Fig. 6 (Bellows). Paralysis of the orbicularis oculi following shell injury in the parotid region.

Fig. 7 (Bellows). Pulsating exophthalmos resulting from shell injury. A, Point of entrance. B, Point of exit.

rectly as a result of injuries to nerves or blood vessels supplying the globe and its adnexa. Thus, Horner's syndrome follows injury in any portions of the sympathetic such as in wounds of the neck (fig. 5). Paralysis of the orbicularis oculi results from injury to the facial nerve (fig. 6). Pulsating exophthalmus may follow an injury which ruptures the internal carotid artery in the sinus cavernosus (fig. 7).

In the 40 cases of ocular alterations produced by indirect injuries, the chief ocular lesions were intraocular hemorrhage and changes in the vitreous, choroid, retina, and optic nerve (see table 4).

DIRECT OR CONTACT OCULAR INJURIES

A direct or contact injury is produced by the impact of a missile upon the eyeball. Contusion, perforation, penetration (with or without retention of a foreign body), laceration, or avulsion are forms of direct or contact ocular injuries that were observed. Frequently secondary missiles, such as debris, sand, gravel, wood, or glass, set in motion by the explosion, cause far more damage than the primary missile (fig. 8).

If the impact of the missile is of insufficient force to cause perforation, penetration, or rupture, it produces signs and symptoms of a contusion injury. When

Fig. 8 (Bellows). Injury to face, lids, and eyes produced by secondary missiles (debris and sand).

the force is adequate, the missile perforates or penetrates the globe or causes a rupture of the eyeball. At times the missile carries away part or all of the eyeball, thus producing a partial or total avulsion of the globe.

Bullets produce more severe ocular injuries than do fragments of shells, mines,

or grenades. Thus, in World War I, according to Mills,²³ not more than 25 to 30 percent of ocular casualties caused by bullets were saved, while about 60 percent of shell injuries were saved. In the 198 direct eye injuries by shells, grenades, and mines in the series reported in this paper, enucleation was necessary in 105, or 53 percent. In 25 cases of direct injury by bullets, 16, or 64 percent of the eyes were lost.

The disorganization of the globe when struck directly by a velocity projectile is caused by the propagation of the velocity of the projectile to the globe with its incompressible fluids. Mills states that "velocities being equal, the smaller the eye, the greater the destruction." Harvey and others²⁴ have recently shown that when a velocity missile strikes soft tissues it results in a series of phenomena comparable to that observed in water or a gel. The liquid is first compressed. This area of compression precedes the missile as a shock wave. The missile forces the media aside as well as forward, thus producing a conical cavity. In the tissues, the cavity fills with blood and tissue debris. Blood extravasates into the tissue spaces. In the region away from the cavity the chief damage is the rupture of the capillaries.

NONPENETRATING OR CONTUSION INJURIES

Contusion injuries caused by the impact of missiles vary from a slight corneal abrasion or foreign body embedment in the cornea, conjunctiva, or sclera to rupture of the globe. Contusion injuries are produced chiefly by a nonpenetrating direct or glancing blow by a missile. Markelova²⁵ reports that 58 percent of ocular military injuries are nonpenetrating. Under the term "the traumatic syndrome of the anterior segment of the eye," Frankel²⁶ groups the symptoms and findings

of contusion injury as follows: Hyphema, deep anterior chamber; changes in the iris consisting of tears, iridodiolysis, rupture of the pupillary margin, iridodonesis; pupillary alterations, mydriasis or deformity; dislocation and cataract formation of the lens. Leplat,²⁷ in an experimental and clinical study of contusion injuries, reports that following a contusion there is a variation in ocular tension, an increased protein content in the aqueous humor, spasmodic miosis, and congestion of ciliary and conjunctival vessels.

Hypotony is a frequently occurring symptom. DeSchweinitz²⁸ warns against the common conception that this finding necessarily signifies a perforating wound. Collins²⁹ believes the decreased tension is due to escape of intraocular fluid through expanded exit channels or to arrest of secretion because of paresis of intraocular nerves. According to this author, hypotony causes some of the conditions ordinarily ascribed to trauma. Striate keratitis and pigmentary changes in the choroid and retina are caused by the wrinkling of the elastic lamina of the cornea and choroid, respectively. Frequently overlooked, according to Kilgore,³⁰ are the alterations in the ciliary body after contusion of the globe. Edema, round-cell infiltration, pigment migration, and scar-tissue formation are observed in the ciliary body after several days. These changes explain some of the permanent visual disturbances following a blow of moderate degrees. The lesions resulting from contusion injuries in warfare differ from those seen in civilian life because the velocity of the striking force which causes war injuries is so much greater. Twenty-seven individuals out of the 300 cases received ocular injury by contusion. The following lesions were observed in this group. In 11 eyes, the chief lesion was in the posterior seg-

Fig. 9 (Bellows). Contusion injury causing changes in pupil and lens.

Fig. 10 (Bellows). Corneal scar following a contusion.

ment—six eyes showed chorioretinitis; one, macular hole; one, choroidal rupture; two, optic atrophy; and one, avulsion of the optic nerve. There were six cataracts; in one eye, the cataractous lens was dislocated (fig. 9). In four eyes, the main alteration was in the cornea, resulting in opacities (fig. 10). The visual acuity resulting from contusion injuries is shown in Table 5.

PENETRATING INJURIES OF THE GLOBE

Penetrating injuries are more likely to involve the cornea than the sclera. Savin and others³¹ found that of 36 patients all but five had corneal or corneoscleral injuries. According to Verhoeff,³² the flying missiles strike the pupillary area less often than other parts of the cornea because the former makes up only a small part of the total corneal surface.

The lesions produced by a missile which perforates the ocular coats or penetrates

Fig. 11 (Bellows). Penetrating injury of the globe by a high-velocity-shell particle.

deeply into the globe are usually severe (fig. 11). The more serious lesions characterized by the collapse of the globe are considered with lacerations and ruptures of the eyeball. The changes resulting

from a penetrating ocular injury vary according to the size and velocity of the traumatizing agent, the depth of penetration and the site of the wound.

With the exception of very small wounds, a corneal perforation causes an outrush of aqueous, which carries the iris forward. Frequently the iris is incarcerated in the corneal wound or may actually prolapse out of the wound. The lens very often becomes opaque. Hemorrhage either occurs in the track of the missile or is more widespread within the

jects into the vitreous. Some darkly pigmented areas may cover part of the mass.

Corneoscleral penetrations offer the gravest prognosis, for in these cases both the anterior and vitreous chambers are opened with subsequent loss of aqueous and vitreous and exposure to infection. Prolapse of iris, ciliary body, and vitreous are common complications. Subluxation of the lens follows injury to the zonule. When the injury is in the ciliary region, there is a distinct danger of

* Some globes showed two or more serious lesions.

globe. Choroidal and optic-nerve lesions are produced either because the penetrating agent strikes these structures directly or because the structures undergo early or late changes due to edema, inflammation, hemorrhage, or infection. Traumatic proliferative choroiditis is a condition frequently observed in wartime. Michaelson and Kraus³³ observed such lesions in 6 of 7 cases in which a double penetrating injury was incurred. If the media is clear, a white mass is observed in a choroidoretinal atrophic area. The mass appears solid and pro-

sympathetic ophthalmia, particularly if prolapse of the iris and ciliary body is present.

There were 206 eyes with penetrating injuries in the 300 cases in this series. The injuries in 104 of these were so severe that enucleation of the globe was required shortly after the injury. This group is considered with avulsions, ruptures, and lacerations of the eyeball. Furthermore, there were 65 eyes in which the penetrating injuries were complicated by retained foreign bodies; these are considered in the section of intraocular

foreign bodies. There were 37 eyes with a penetrating injury in which the foreign bodies were not retained. Table 6 presents the ocular lesions observed in the latter cases.

RUPTURE OF THE EYEBALL

Rupture of the globe, including laceration and partial avulsion of the eyeball, produces the clinical features of a collapsed and disorganized eyeball. If observed early, there is a marked swelling of the lids, severe chemosis, and limitation of motion. The latter is due to retrobulbar hemorrhage. Lister¹⁶ distinguishes between rupture of the globe resulting from a blow by a slowly moving body, which strikes the eye directly, and rupture arising from an injury produced by a missile travelling at a great velocity through the orbit. In the former instance, the break occurs "in the equator around the line of impact, at a point where the globe is least supported;" in the latter type, the force is transmitted to the globe and causes rupture, usually at a point of contrecoup. Finally, rupture of the eyeball may be caused by a missile passing through it. If the projectile is large and is travelling at a high speed, it may cause an extensive laceration of the globe or

Fig. 12 (Bellows). Fracture of orbit, rupture of eyeball, and laceration of lids and surrounding soft tissues caused by a high-velocity-shell fragment.

even avulsion of the eyeball. There were 105 eyes belonging to this group of trauma, all of which required primary enucleation or early secondary enucleation. In all but 36, there were wounds of the surrounding soft tissues, fracture of the orbit, or intraorbital foreign bodies (see table 7 and fig. 12).

INTRAOCULAR FOREIGN BODIES

Penetrating injuries with a foreign body retained within the globe form both a large and an important proportion of ocular casualties. Dansey-Browning³⁴ reports 67 cases of intraocular foreign bodies in a series of 514 ophthalmic battle casualties.

Stallard³⁵ reported 105 cases of intraocular foreign bodies and found that the right eye was injured in 41 cases, the left in 34, and both eyes in 30. As in all types of penetrating injuries to the eyeball, the cornea is the most frequent site for the entrance of the foreign body. In 56 of Stallard's cases, the foreign

body entered through the cornea; in 42 through the sclera; and in three cases the foreign bodies were multiple and entered the globe through the cornea and sclera. Trevor-Roper³⁶ found the site of entrance to be through the cornea in 100 eyes, across the limbus in 11, and through the sclera in 15. Scott and Michaelson³⁷ stated that 76 out of 301 ocular casualties suffered from intraocular foreign bodies. There were two bilateral cases. The wound of entry was through the cornea in 37 percent; the limbus in 33 percent; the sclera in 26 percent; and undetermined in 4 percent.

Intraocular foreign bodies were found in 65 eyeballs in this group of 300 soldiers with a total of 352 eye injuries. The left eye was involved in 32 cases, the right eye in 29, and both eyes in two. The reason for the small number of bilateral involvements observed at this hospital is that soldiers with bilateral eye injuries with visual acuity in the better eye of 20/200 or less were sent to other installations. Those eyes with foreign bodies which were so badly disorganized as to require primary enucleation are not included here.

The intraocular foreign bodies encountered in military ophthalmology differ from those observed in civilian or industrial practice in that bilateral involvement is more frequent and that the particles are usually smaller, multiple, and nonmagnetic or weakly magnetic. In contrast to the smooth surfaces of chips from punches, hammers, chisels, and so forth, which cause a great number of industrial cases, fragments from projectiles are generally irregularly shaped, with ragged edges and rough surfaces.

Shell and bomb fragments are generally magnetic but of low degree, while fragmentations of grenades, booby traps, and land mines are poorly magnetic or not at all. There is a wide divergence

of opinion as to the proportion of magnetic to nonmagnetic foreign bodies. Comparing 125 cases of intraocular foreign bodies due to war injury with as many case of industrial injuries, Pokrowsky³⁸ found that only 45 percent of the former group were magnetic as compared to 85 per cent in the latter group. In 78 cases reported by Gasteiger and Schmidt,³⁹ they found only four that responded to the magnet, and of these, two were industrial war injuries and not field injuries. Stallard,³² in 105 cases of intraocular foreign bodies, found 66 were nonmagnetic and 39 were magnetic, of which the majority were magnetic to only a slight degree. Wiener,¹³ too, remarks upon the extremely low incidence of magnetic intraocular foreign bodies encountered in World War II.

The intraocular foreign bodies are nearly always of small size. The reason for this is that the larger projectile, because of its high velocity, disorganizes the eyeball to such a degree that immediate enucleation is required. Stallard³² found the majority of foreign bodies measured 2×3 mm., or less. The foreign bodies were measured in 19 eyes in the series reported herein, and it was found that 16 were 2 mm. or less in the largest dimension. The three largest particles were 1×3 , 2×4 , and 5×6 mm.

The clinical features produced by intraocular foreign bodies depend upon such factors as the number, size, and location of the foreign body; the presence of intraocular hemorrhage; infection or prolapse of vitreous, lens, or uveal tissue; and alterations in the media, fundus, and optic nerve. Another important factor is whether the foreign body is well tolerated or whether it calls forth an inflammatory reaction. Depending upon these conditions, the lesion produced by a foreign body may be very slight or so extensive as to require enu-

cleation of the eyeball. If the wound is recent, examination may reveal the point of entrance. Slitlamp examination in some instances reveals the path of the foreign body and the place of lodgement. A small perforation through the sclera frequently escapes detection. A foreign body lying within 3 mm. from the center of the cornea is considered to be anterior to the lens; if it is situated between 3 and 7 mm., it lies within the lens; between 7 and 24 mm., it lies within the vitreous humor.

If the eye is preserved and the foreign body is retained, other symptoms may arise, depending upon the nature of the foreign body. Particles rich in iron differ from other intraocular foreign bodies in that they are magnetic and are capable of producing siderosis bulbi. Since iron and iron-containing foreign bodies are usually removed early, siderosis is seldom observed. In this series of 65 cases of intraocular foreign bodies, only three eyeballs showed siderosis bulbi. Copper also deserves special mention since it frequently produces either severe purulent reaction or chalcosis bulbi. Chalcosis bulbi was present in two soldiers. In one, a nonbattle injury, the lesion was bilateral; in the other, only one eyeball was involved. Mickle⁴⁰ reports that aluminum, which produces an abscess in the skin, is paradoxically well tolerated in the eye. Wiener,⁴¹ agreeing with this observation, recommends that no attempt be made to remove intraocular foreign bodies of aluminum. Minute particles of rock, glass, and lead are well tolerated by the eye.

Table 8 shows the most important pathologic lesions resulting from 65 cases of intraocular foreign bodies. Some eyes showed multiple severe lesions. The most common causes for the loss of visual acuity in eyes which have been injured by an intraocular foreign body are cataract; corneal opacities, including adher-

ent leukoma, intraocular hemorrhage, and vitreous opacities; phthisis bulbi; and lesions in the iris, retina, and choroid.

A factor of prime importance in the proper management of intraocular foreign bodies is accurate localization. Fortunately, most intraocular foreign bodies

* Some eyes showed two or more serious lesions.

resulting from war injuries cast a shadow on X-ray films. The two chief exceptions are the secondary missiles, stone and glass, and even these are detectable by special methods such as Vogt's⁴¹ bone-free technique. Bone-free roentgenograms as recommended by Vogt are of particular value if the foreign body lies in the anterior 8 to 12 mm. of the globe. Since the apex of the cornea or the plane of the corneal limbus is used as a point of reference, it is sometimes difficult to determine if a foreign body near the posterior pole lies in or out of the eyeball. Moreover, it is well-known that refractive errors and variations in the size of the eyeball make for the possibility of error. In such cases the injection of air (Spackman⁴²) or oxygen (Scheie and Hodes⁴³) into Tenon's capsule gives valuable information.

In some cases, the Berman Metal Locator was of considerable value in localizing the intraocular foreign bodies. Since the instrument yields a response only if the probe is very near to a magnetic particle, a negative reaction does not preclude the possibility of the presence of a non-magnetic foreign body, for the magnetic foreign body may be deep within the globe.

The posterior surgical approach was employed in nearly all instances. The great advantage of this method, an advantage that outweighs all possible disadvantages, is the fact that it places the magnet as near the foreign body as possible. This was particularly desirable because the foreign bodies were frequently poorly magnetic. The sclerotomy wound was always ringed with diathermy applications as a safeguard against retinal detachment.

In the series of the 65 eyes with intraocular foreign bodies herein reported, 29 were magnetic and were removed. In four eyes however, one or more other particles remained within the globe, indicating that a combination of magnetic and non-magnetic foreign bodies existed in the same eyeball. In 36 eyes, the foreign body did not respond to one or more attempts at removal with the magnet and were considered nonmagnetic. In some instances, subsequent enucleation of the eye confirmed the nonmagnetic nature of the foreign bodies.

The following summarizes the results: In 20 cases, the eye was finally enucleated; in four, the eye, although preserved, was totally blind; in 22, visual acuity was less than 20/200; in 13, visual acuity was between 20/200 and 20/40; in six, visual acuity was 20/30 or better.

NOTES, CASES, INSTRUMENTS

PRESSURE EFFECTS IN CONTACT LENSES

JOSEPH I. PASCAL, M.D.
New York

The first contact lenses, the Müller lenses, were made by a glass-blowing process, similar to that for making artificial eyes. Neither the corneal section nor the scleral section of these lenses was made with any degree of scientific accuracy. In spite of this, however, the occasional successes which these lenses afforded, especially in cases of conical cornea, spurred on further research. The next step was completely opposite, the Zeiss glass ground lenses in which both the corneal section and the scleral section were ground with scientific precision.

The corneal section perfected by precision grinding more than 30 years ago has not been improved upon except that the corneal section is now made of plastic. The scleral section, however, ground as it was on spherical tools gave but a limited number of successful fittings. Subsequent improvements in contact lenses concerned themselves chiefly with perfecting the scleral portion so as to make the lens more comfortable to the wearer.

As the spherically ground scleral section did not prove satisfactory in most cases, a toric system of scleral curves was designed. These yielded a greater number of successful fittings than the spherical curves had, but they still fell far short of solving the problem of a comfortable scleral fit.

The idea was then conceived that if the scleral portion of the lens was made from a mold or impression of the eye it would give a good comfortable fit. The idea seems reasonable, but in practice has not worked out. Most of the lenses made

from a mold exert too much pressure on the eye and a great many are uncomfortable. This occurs in spite of numerous adjustments, stretching over months and months, during which the lenses are ground out, tightened, loosened, and so forth.

In the search for a better scleral section, the idea was conceived to make the bearing surface of the scleral section a portion of a cone. A lens was designed so that the bearing, conic section touched the sclera on a tangent, resting only on a narrow rim of 1 to 2 mm. This has proved very satisfactory and caused a revision of one of the cardinal principles which governed contact-lens fitting.

From the earliest days of contact-lens fitting, it has been assumed that the larger the bearing surface of the lens on the eye the more comfortable the lens would be. The idea was that the larger bearing surface would distribute the pressure over a larger area of the eye and thus produce minimum pressure everywhere.

But the idea, plausible as it sounds, is based on a fallacy, as the following illustration will show. If we take a 20-pound weight and place it on one square foot of a table, 20 square feet in area, this square foot of the table will be under a pressure of 20 pounds, while the rest of the table will be under no pressure. The table will suffer some distortion because of the uneven pressure on it. If we now break up the 20 pound weight into 20 parts and place each pound on one square foot of the table, the pressure will be evenly distributed and the table will suffer no distortion. This is perfectly true of gravity pressure.

The pressure of a contact lens on the eye, however, is not gravity pressure. It is an adherent force or adherent pressure,

for want of a better term. Such adherent pressure interferes least with the functions of the eye when it is limited to a small area. In other words, the principle is reversed. The smaller the bearing surface exerting this adherent pressure, the more comfortable the lens is on the eye. This principle is utilized in the tangent-cone contact lens. The bearing surface of the scleral portion is part of a cone which rests tangentially to the eyeball. It is adherent only over a narrow rim of 1 to 2 mm.

The clue to this principle of fitting came from observations made on impression molded lenses. It was found that, when these lenses were adjusted so as to fit the sclera "like a glove," they were more uncomfortable than when they were adjusted so as to have a smaller bearing surface more or less tangential to the eyeball. Following up this clue led to the design of the tangent-cone lens.

PLASTIC VISUAL TEST PLATES

ARTHUR GERARD DeVoe, M.D.

New York

AND

VICTOR H. DIETZ, D.D.S.

St. Louis

Exact measurement of visual acuity is seldom necessary in routine refraction. An approximation is usually all that is needed, since it makes little practical difference whether an individual's uncorrected vision is 20/200 or 20/100, and since the refractionist's ultimate aim is to obtain the best possible corrected vision regardless of which line on the chart this may be.

There are occasions, however, on which it is of considerable importance to have as nearly exact records of visual acuity as is possible to obtain. In the Armed Forces,

for instance, a difference of one line on a test chart may alter a man's physical classification or may disqualify him for a desirable position. In civil life a somewhat comparable situation may arise in compensation cases. Again, in an orthoptic clinic, careful follow-up of cases undergoing occlusion necessitates an accurate and consistently reproducible method of determining vision.

A particular problem is that of individuals who profess to better uncorrected vision than would be expected by the degree of refractive error which they possess. These are usually candidates for positions or schools which require a high standard of visual acuity. A determined patient, aware of poor vision, will often go to extraordinary steps to pass these tests. Memorization of charts and other stratagems are well-known. The usual types of wall charts are of course easily memorized. Projecting instruments lend themselves less readily to memorization in the lines which represent high visual acuity, but there is little chance for the examiner to vary or alternate letters in the 20/100 to 20/400 lines, a region in which critical evaluation may be all important.

As has been pointed out repeatedly, most of the charts now in general use do not remove the factor of recognition inherent where letters or numbers are employed. The need for standardization of test charts has also been emphasized. Most observers¹⁻³ favor some modification of the Landolt ring test, this being a figure which meets the criteria of Snellen in all meridians, including the critical detail of one minute of arc, as well as the gross overall figure of five minutes of arc. The factor of recognition does not enter as it does with letters. It has been stated that the break in the Landolt ring might be detected by its increased luminosity before its form could be actually

distinguished. Nevertheless, its advantages as compared to the other test symbols now in use would appear to outweigh its disadvantages. Fink² has recently described individual test plates printed on round pieces of cardboard and viewed in reflected light at an illumination of 15 foot-candles. Such printed

Fig. 1 (DeVoe and Dietz). Plastic visual test plate in use.*

cards used by the same examiner under the same conditions should produce excellent results. When many copies of any cards are printed, inevitable variations appear in the reflection factor of the background, letter itself, finish of its surface, and type of ink. When the cards become dirty or worn with use, further inaccuracies may appear.

In order to obtain a test which would be practical, accurate, easily adaptable to varying surroundings, and with the par-

* A modification of these plates may be obtained from A. Haustetter, Inc., 2 East 45th Street, New York 17.

ticular factor of being unlearnable, the following plates were devised using both the illiterate E and the Landolt single-break ring (fig. 1).

A diffusion screen was constructed of two layers of 10/1,000-inch double-matte plastacele in such a manner as to readily clamp upon a reflector shield of a standard gooseneck desk lamp. This, when used in conjunction with a 15-watt frosted bulb, has given evenly diffused lighting of about 25 foot-candles in intensity.

Test figures were cut from 10/1,000-inch vinyl copolymer (vinyl chloride and vinyl acetate). These figures were then laminated to $\frac{1}{8} \times 4 \times 4$ -inch lucite plates by use of a laminating press. Lamination was effected at 140° C. for 30 seconds at 4,000 lbs. pressure, and the pressure then increased to 6,000 lbs. for 15 seconds. After release of the pressure, the lucite plates were pulled off the metal plates while hot and allowed to cool on a cold metal pate. The Snellen value of the figures may be conveniently scribed on a corner of the lucite plates by using a metal trylon stylus in a lettering device. Any desired figures can be adapted to this process.

SUMMARY

The visual test plates herein described have the following advantages:

1. They present clear, accurate images under constant conditions of illumination.
 2. They are unbreakable and will withstand use without loss of efficiency.
 3. They are unlearnable.

CILIARY DILATION AND VITREOUS RECESSION IN CATARACT EXTRACTION

MARTIN P. KOKE, M.D.

San Diego, California

After a review of the literature relative to the mechanism of accommodation and a limited amount of experimentation¹ on that subject, it appeared that some of this information might be useful in cataract surgery. During parasympathetic stimulation, the ciliary processes have been shown to move toward the lens and the anterior surface of the vitreous to bulge forward and axialward. There resulted a narrowing of the interval between the lens equator and the ciliary processes. Under the influence of parasympathetic depressants, the interval increased and the anterior vitreous moved posteriorly and centrifugally. It was apparent that parasympathetic depressants enhanced the possibility of a successful cataract extraction by their indirect influence on the vitreous and zonule.

In view of the reports of Cogan² and others, it was accepted that the sympathetic nervous system had a role in accommodation. It seemed logical that sympathetic stimulation should augment the effects of parasympathetic depression; that is, further widen the zone between the lens equator and the ciliary processes and produce added recession of the anterior vitreous.

Neosynephrine hydrochloride* (10 percent) and scopolamine hydrobromide (0.2 percent) were instilled in 80 eyes

preceding cataract extraction. One hour before surgery two drops of scopolamine were instilled on the cornea; 30 minutes later two drops of 0.5-percent pontocaine hydrochloride were instilled, and this was followed in two minutes by the instillation of one drop of neosynephrine. In the operating room, two minutes after the first instillation of 5-percent cocaine hydrochloride, one drop of neosynephrine was again placed on the cornea. Approximately 15 minutes later, local anesthesia was completed and the operation was begun. An O'Brien akinesia and corneoscleral sutures were used in all cases. Six extracapsular extractions were done. The intracapsular method was attempted in the remainder but the lens capsule ruptured in six. In no case was vitreous lost. There was no tendency for the iris to bulge and in many cases its pupillary portion was recessed. The pressure required at the limbus to rupture the zonule was less than ordinarily needed. No patient complained of undesirable systemic reactions.

It is not amazing that there was no loss of vitreous in 80 consecutive cataract extractions, but in no case was vitreous protrusion threatened. The use of scopolamine and neosynephrine appeared to provide increased safety in cataract surgery. The drugs gave maximum pupillary dilation by relaxing the iris sphincter and stimulating the dilator. They widened the interval between the lens equator and the ciliary processes, thus increasing the tension of the suspensory fibers of the zonule. These changes facilitated the manipulation for zonular rupture. The anterior vitreous was actively recessed and a safeguard against its extrusion provided.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

March 4, 1946

DR. MAURICE L. WIESELTHIER, *presiding*

CHARTING OF DIPLOPIA AND MUSCLE ACTION

DR. JOSEPH PASCAL discussed the subject during the preliminary instruction period (Published in this Journal, 1946, volume 29, August, page 1001).

THE OBSERVATION AND CORRELATION OF SCIENTIFIC DATA

DR. ERNEST L. SCOTT said that it is common knowledge that the items of a sample vary among themselves. It is also common knowledge that samples from a given population will differ from each other not only in the value of the mean but in the amount of variation within the sample.

Since one is usually interested in evaluating the population from which the sample is drawn as well as the sample itself, it is desirable not only to describe the sample adequately but to be able to describe the population and so to be in a position to predict the characteristics of further samples drawn from that population. The theory of sampling makes all of this possible.

The fundamental mathematics involved in the theory of sampling need bother one no more than does the formula for his microscope objective. The use of probability paper makes difficult drafting unnecessary. No more complicated apparatus than a ruling pen and a straight edge are needed to display the characteristics of a sample fully in a chart. Given the

mean and standard deviation of an appropriate and adequate sample, one not only can describe that sample concisely but one also can predict the properties of further samples within stated limits, as well as the characteristics of the population from which the sample is taken. This implies the possibility of assigning a degree of probability that a single further item does or does not belong to the population; that is, whether the patient in the office is or is not normal with respect to the property being measured.

Since the description of a sample is mathematical, samples can be readily compared either by difference or by ratio, and the precision of the comparison can be stated. This makes for the convenience of the investigator in evaluating his data, and for the clarity and ease with which the report can be read. It also permits precise comparison of the work of different investigators who have reported their work in this form. The measures of variation will make conclusions more exact and will safeguard the reader against over-enthusiasm on the part of the author. Data treated systematically in this impersonal manner can hardly carry any tinge of bias.

If samples are to do all this satisfactorily, they must be both adequate and appropriate. Evidence is presented that when an appropriate sample approaches 50 items its statistics follow the requirements of the theory in a satisfactory manner.

The determination of appropriateness is more difficult. The sample must be homogeneous. The lack of homogeneity was illustrated in the early figures for CO₂ tension of the blood. The figures determined at sea level would not fit at high

altitudes. A method for homogenizing a sample was described.

Discussion. Dr. Percy L. Fridenberg said that Dr. Leo Burger observed symptoms in patients in the same age group (30 to 40 years), numbering over 100 cases, and tabulated them according to age, occupation, weight, and so forth. There was interference with the circulation of the lower extremities, and observation revealed thrombosis and obstruction of the blood vessels; that is, thrombo-angiitis obliterans. Ninety-five percent of these patients were tailors who sat with their legs crossed, smoked a great many cigarettes, and drank large quantities of tea. All of these symptoms can be considered as causative factors.

SYSTEMIC FINDINGS IN RETINITIS PIGMENTOSA

DR. ISADORE GIVNER and DR. MAURICE BRUGER said that a study of 14 patients with retinitis pigmentosa gave the following results and conclusions:

1. No abnormalities in pulse rate, blood pressure, or temperature were observed.

2. The serum cholesterol was within normal limits in 7 of 11 patients in whom this determination was made. In three, it was only slightly elevated.

3. The basal-metabolism rate was within normal limits in 8 of 12 patients. In four, the rate varied from 15 to 21 percent below the average normal.

4. Each of 11 patients had creatinuria. This series included eight males and three females.

5. The spinal-fluid pressure was increased in 3 of 12 patients, but most of the other readings bordered on the upper limit of normal rather than on the lower levels. In 3 of 12 patients, the total protein content of the spinal fluid was definitely increased. In the remainder, normal values were observed.

6. Liver damage was not demonstrable in any of the 12 patients investigated.

7. The fasting vitamin-C content of the plasma was reduced in 7 of 9 patients in whom this determination was carried out. The two patients with normal findings had been taking cevitamic acid before the test was carried out. In seven patients, vitamin-A studies on the serum gave normal values.

8. In each of 11 cases, pupillography showed tonohaptic reactions and other evidences of diencephalic disorders.

9. Blood analysis for urea nitrogen retention and urine specific gravities after the administration of pitressin failed to reveal any measurable impairment in renal function in 13 patients.

10. Physical examinations including neurologic studies were essentially negative, except for the high incidence of high-arched palates and nerve deafness as revealed by audiometric tests. Seven of eight patients thus studied revealed impairment of hearing. Two patients were deaf mutes.

11. In two patients, microscopy failed to reveal any abnormalities in the capillaries of the finger bed.

Discussion. Dr. Otto Lowenstein found, in 1938, in collaboration with Franceschetti, the presence of tonohaptic pupillary reactions in retinitis pigmentosa and also in adiposogenital dystrophy, as well as in some chronic postencephalitic and catatonic conditions. Later, it was shown, experimentally and clinically, that tonohaptic pupillary reactions were due to lesions in the posterior (sympathetic) part of the hypothalamus and its connections to the midbrain, and that symptomatically they were due to a central weakness of the sympathetic. The significance became more evident in the light of experiments on the relations between endocrine glands and their autonomic control. When pituitary glands were im-

planted into pigeons or small mammals, or when antuitrin S was injected into human beings, increased parasympathetic activity resulted and could be shown pupillographically.

These facts, in combination with our knowledge of the melanophore-expanding hormones, may perhaps throw some light on the mechanism involved in the production of retinitis pigmentosa. Experimental work indicates the following schematic and tentative mechanism:

Inhibition of the sympathetic center, as indicated by tonohaptic pupillary reactions, causes a relative parasympathetic hyperactivity, stimulating pituitary action and resulting in, among others, the production of an increase of melanophore-expanding hormones. This increase in turn stimulates the parasympathetic centers in the interbrain. These parasympathetic centers in turn powerfully stimulate the pituitary to produce melanophore-expanding hormones, probably acting on the retina pigment and, independently, stimulating the interbrain, thus closing a vicious circle.

Dr. Von Sallmann asked: (1) How many patients of the series presented by Dr. Givner showed obesity and hypogenitalism in addition to other diencephalic pituitary signs? (2) Does Dr. Givner see any similarity between retinitis pigmentosa and the destruction of the retina induced by iodate? (In Dr. Sallmann's opinion there is none—either in patients with iodide-iodate intoxication or in the experimentally produced lesion in rabbits.) (3) Does Dr. Lowenstein's theory on the mechanism in the diencephalic disturbance explain the cases of retinitis pigmentosa with intestinal spasm which are relieved by adrenalin? (4) Did the X-ray examination of the sella show an abnormality in Dr. Givner's series?

Dr. Givner said that Dr. Bruger's and his findings are not in disagreement with

Dr. Lowenstein's theory of the pathogenesis of retinitis pigmentosa. Tendencies toward the lower limits in the basal-metabolism rate and toward low vitamin-C content are commonly found in vagotonia.

In answer to Dr. Von Sallmann, only their first case showed obesity and other clinical evidences of pituitary dysfunction. In regard to Kalt's experiment of injecting sodium iodate, they do not believe retinitis pigmentosa was produced, but a pigmentary disturbance of the retina was. Because Kalt felt that liver disturbance may be present in retinitis pigmentosa, they did the sensitive cephalin flocculation tests and found them negative.

In answer to the question regarding relief of intestinal spasm by adrenalin in cases of retinitis pigmentosa, the stimulation of the sympathetic might well counterbalance the vagotonia suggested by Dr. Lowenstein's theory. Finally, X-ray examination of the sella was not done routinely, but in those cases where it was, normal findings were encountered.

OCULAR CHANGES IN RATS ON AMINO-ACID (VALINE) DEFICIENT DIET

DRS. ARMANDO FERRARO and LEON ROIZIN described experiments in which young and adult rats (Sherman's stain) of the same sex (male), age, and litter were reared on a slightly modified valine-deficient diet as described by Rose.

The duration of the experiments lasted from 2½ to 4½ months. Five or six weeks after the experiments were started, the rats on valine-deficient diet developed, in addition to general changes and structural alterations of other organs which are still objects of microscopic studies, corneal changes leading to opacities. These seemed to be the results of edema, hyperplasia, and progressive degeneration of the epithelial cells leading gradually to keratinization and disorganization, most-

ly of the superficial layers of the interpalpebral cornea. In addition, pronounced vascularization was observed. Slight changes of the lens, characterized mostly by vacuolization of the cortex, were only occasionally noticed.

These structural changes of the eye appeared to be reversible in character, if treated in time, as demonstrated by the marked improvement following the administration of the synthetic valine to the animals on valine-deficient diet. This condition is being described as "nutritional corneal dystrophy" until further investigations are completed.

Discussion. Dr. Isadore Givner said that the amino-acid requirements for man may differ both qualitatively and quantitatively from those of the rat so that direct application to man of the results of experiments on animals cannot always be made.

Since there is, as yet, no suitable and reliable laboratory method for the detection of specific amino-acid deficiency, studies such as this are of importance. Eight of the 22 amino acids found in proteins have essential specific functions, yet they cannot be synthesized by the body. Hence, specific amino-acid deficiencies may occur, and it may fall to the ophthalmologist to detect early valine deficiency.

In general, proteins are important in the osmotic relation between intracellular and extracellular fluid. Although edema is not the earliest result of protein deficiency, it is, in our present state of knowledge, about the first clinical sign of deficiency. It is not surprising that the first change observed in the cornea in valine deficiency is edema of the corneal epithelium. Interestingly enough, the edema is usually confined to the interpalpebral area. In one case, however, a bulbous keratitis developed in the center of the cornea, while edema of much

less degree was found over the remainder of the cornea. Following this change as the deficiency progressed, the most superficial layer became keratinized and in one instance showed stippling after fluorescein was instilled and irrigated out. The edematous process is reversible.

The vascularization is very interesting in that it is all deep, starting as an arcade at the periphery and then becoming extended into the deep stroma. This is in marked contrast to tryptophan deficiency in which the vascularization is superficial. Under treatment, the lumen becomes reduced in width and becomes bloodless. The changes in the lens are minimal. In some of the cases studied, no opacities were found; in others, they were found only in the anterior portion of the cortex and were not sufficient to obstruct ophthalmoscopic study. The remainder of the eye was normal. This was verified on histologic study.

HYDROGEN-ION CONCENTRATION OF THE AQUEOUS

DR. LUDWIG VON SALLMANN used two glass electrodes, especially designed for measuring the pH of the intraocular fluids in vivo. For determination of the hydrogen-ion concentration in the aqueous, the electrode consisted of a micro-papillary and was armed with a fine needle which was inserted into the anterior chamber. The pH of the vitreous was determined with a membrane electrode. Great care was taken to avoid erroneous readings due to the uncontrolled escape of carbon dioxide and due to inaccuracies in temperature control. It was found that the anatomic conditions of the eye were extremely well-suited for this type of in vivo procedure. The physiologic pH of the aqueous fluid in rabbits ranged between 7.44 and 7.49 at the early phase of general anesthesia with a barbiturate. Local anesthesia and pro-

longed general anesthesia altered the pH of the aqueous inversely; that is, local anesthesia caused a shift to the alkaline side, and general to the acid side. Diets rich in alkali and the introduction of anions into the aqueous by ion transfer did not cause significant changes. A definite but moderate shift to the acid side occurred in the aqueous when the vitreous was the site of a bacterial infection. The use of the electrodes and the technique designed for the determination of the pH in vivo gave information unobtainable with other procedures on the hydrogen-ion concentration of the aqueous and vitreous in physiologic and pathologic conditions.

INFLUENCE OF SYMPATHOMIMETIC DRUGS ON THE REGENERATIVE PROCESSES OF THE OCULAR EPITHELIA

GEORGE K. SMELSER, PH.D., studied the effect of topical applications of a number of sympathomimetic drugs on mitosis in the corneal epithelium of 87 animals to determine if they were similar in their action on this process. Epinephrine, neosynephrine, ephedrine, benzedrine, and privine were used in addition to pitressin, which was included because of its action as a vasoconstrictor. Four of these compounds, applied topically to the eyes of rats at hourly intervals, caused a marked decrease in cell division in corneal epithelium. Pitressin and privine lacked this effect, although they caused a prolonged blanching of the conjunctiva.

No mitotic inhibition was noted in the conjunctival epithelium of the epinephrine-, benzedrine-, and neosynephrine-treated animals in which a marked depression of mitosis in the corneal epithelium was demonstrated. Privine and pitressin were without effect on mitosis in the conjunctiva but ephedrine (0.5 percent) inhibited cell division significantly in two thirds of the animals.

These drugs were also applied topically at two-hour intervals to standard thermal burns of the cornea in order to determine their effect on regeneration of the corneal epithelium. All of the compounds caused some delay in healing, but this was very slight in the case of epinephrine (1:2500) and pitressin. The only extreme delay in healing was caused by privine, an unfortunate paradox, in view of the entire absence of harmful effect of this drug on mitosis in the intact cornea.

Leon H. Ehrlich,
Recording Secretary.

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

March 12, 1946

DR. T. S. LEATHERWOOD, *presiding*

METASTATIC ENDOPHTHALMITIS

DR. P. M. LEWIS and DR. G. M. WALLACE reported the case of M. C., a 17-months-old colored girl, who was seen on the Ophthalmological Service of the John Gaston Hospital on January 28, 1946.

The anamnesis as given by the mother was that for a week or 10 days prior to the onset of the present illness the child had been receiving injections for relief of painful joints. The nature of the medication was not learned. Forty-eight hours before admission, her left eye became red and the lids seemed to close slightly. No other pertinent information was elicited; however, the hospital records revealed that the child had a nonspecific vaginitis at the time of birth.

Examination revealed the girl to be normal except for the left eye. The lids of this eye were normal in structure but partly closed; the conjunctiva and episcleral tissues were highly and diffusely inflamed; the iris and lens could not be

identified as such; the tension was normal, as were the extraocular movements.

Treatment instituted upon admission consisted of the administration of 10,000 O.x.u. of penicillin every 3 hours; 5 gr. sodium salicylate, 4 times daily; warm boric-acid compresses for 15 minutes, 4 times daily. Atropine-sulfate ointment (1 percent) was applied once daily. In 24 hours, the condition had so changed that the periphery of the iris could be seen. At this time it was felt a metastatic endophthalmitis was present. The following laboratory tests were made, and the results revealed the urine to be normal; red blood corpuscles to be 3,780,000 per c.c.; white blood corpuscles to be 11,950 per c.c.; a blood culture to be negative on the fifth day of incubation; a smear from the vagina to have no pathogenes. X-ray studies of the chest reported a right sided broncho-pneumonia. Consultation with other departments did not reveal any obvious foci of infection.

Six or seven days after admission the hypopyon cleared entirely, and two narrow, posterior synechiae were present at the 12-o'clock position. Later these synechiae disappeared. The pupil became widely dilated, and the lens appeared to be uninvolved; however, it was then possible to see a white, dense mass filling the vitreous body immediately behind the lens. The eye lost the greater part of its angry appearance as well as some of its normal ocular tension, but it did not become exceedingly soft.

The patient did not appear to be acutely or seriously ill. Her appetite was fair. Her temperature was elevated only during the first five days of hospitalization, during which time it did not exceed 101° F. She was seen last on February 13th, three days after discharge from the hospital, at which time her condition was slowly improving. Because of the extreme youth of the patient, it was not possible

to determine the degree of vision present in the eye.

TRAUMATIC OCCLUSION OF THE CENTRAL RETINAL ARTERY

DR. P. M. LEWIS and DR. G. M. WALLACE presented the case of R. F., an 11-year-old colored boy who was seen on the Ophthalmological Service of the John Gaston Hospital on March 4, 1946.

The history revealed that 24 hours before admission to the hospital the boy had accidentally fallen upon a stick, and the force of the fall had been sustained by the left orbit and its contents. A very small quantity of blood escaped the wound; pain was severe momentarily but subsided in a short time; amaurosis developed immediately and persisted in the left eye. Other information was not pertinent to the present illness.

With the exception of the findings in the left eye and orbit, the physical examination revealed a healthy child. The anatomy and functions of the right eye were normal. The palpebra of the left eye were moderately swollen. Superficial abrasions, present at the junction of the mesial and middle thirds, were directed vertically in their greatest length. There was minimal ecchymosis of the lids. The extraocular movements were normal in all directions except temporally. Limitation in this direction was accompanied by pain. The tension of the left eye did not feel abnormal to palpation. A subconjunctival hemorrhage measuring 6 to 7 mm. in diameter was present over the area of the tendon of the lateral rectus muscle. The cornea glistened normally and did not show any abnormalities. The anterior chamber and aqueous were also found to be normal. The pupil was moderately dilated. It did not respond to light and dilated widely when 4-percent cocaine and 1:1000 adrenalin-chloride solutions were instilled. The pupillary response was

not determined with the use of miotics. No structural abnormalities of the iris could be detected; however, the patient was not subjected to slitlamp examination. Although the vitreous and retina contained numerous dense hemorrhages, there was nothing unusual about the lens. The hemorrhages in the vitreous were quite dense and well-defined, and they appeared to be limited by some organic structure or membrane which prevented their diffusion throughout the entire vitreous body. The masses of blood could be seen to be slowly gravitating in mass toward the dependent positions after agitation; one large, dense mass was localized immediately anterior to the papilla and precluded visualization of that structure. The retinal hemorrhages were irregular in size, shape, density, and location. The retina throughout most of its extent was quite white and edematous; however, the inferior nasal quadrant in the area of the equator of the globe had an almost normal coloration. Immediately adjacent and inferiorly to this there was evidence of a retinal separation. Observation at first showed the veins to be full and the arterioles absent of blood except in a few sites where the "cattle-truck" effect was present. Forty-eight hours later fundal examination revealed the veins in certain areas to be entirely absent of blood, the "cattle-truck" effect also present in the veins, and the arterioles unchanged in appearance. The expected macular abnormality was present.

Routine-laboratory urine and blood findings were normal; light perception remained absent; the intraocular pressure variation was not pathologic; and the patient was discharged without treatment from the hospital on March 7, 1946, and sent to the out-patient ophthalmological service to be followed for further observation.

CYST OF THE IRIS

DR. PHILIP MERIWETHER LEWIS presented a patient on whom he had recently operated for a large iris cyst. The patient, a white man aged 26 years, had had his left eye injured, in 1938, by a piece of steel which was removed by operation. The vision was almost entirely lost by this accident. The patient was first seen at the Eye Clinic of the University of Tennessee in January, 1945. He was having severe pain in the left eye which was highly inflamed, with a steamy cornea and tension of 50 mm. Hg (Schiotz). A grayish mass filled a large portion of the anterior chamber. Vision was perception of light only. The patient was admitted to the John Gaston Hospital for treatment and probable enucleation. When the cornea cleared slightly, it could be seen that the gray mass was a large cyst of the iris and that the lens was completely opaque.

Removal of the cyst was attempted, but was only partly successful. The cataract was removed in its capsule. Following this the eye did well for several weeks, but the cyst reformed and grew rapidly, extending from the 4- to the 6-o'clock positions and upwards above the center of the cornea. On March 9, 1945, a keratome incision was made just above the temporal border of the cyst. The incision was enlarged with scissors downwards to the 7-o'clock position. The cyst was removed with forceps and scissors. The eye has been comfortable since operation. Uncorrected vision was the counting of fingers at about three feet.

DIATHERMY TREATMENT IN RETINAL ANGIOMATOSIS

DR. PHILIP MERIWETHER LEWIS presented Mrs. M. P., aged 34 years, a white woman, upon whom he had operated for angioma of the retina.

The patient was first seen in July, 1944, while she was confined to the John Gaston Hospital for general medical studies to find the cause of severe headaches. The angioma was found when the fundi were examined for possible papilledema. Complete general physical and laboratory examinations were negative and the consulting neurosurgeon felt that there was no evidence of cerebellar involvement. The right eye was normal. The disc of the left eye was slightly blurry. Below the disc, two very large blood vessels coursed tortuously downward and forward to a tumor mass in the 6-o'clock median, between the equator and the ora serrata. The tumor mass was about $1\frac{1}{2}$ times the size of the optic disc and of a light, reddish-brown color. The retina surrounding the tumor mass was not detached. Vision was: O.D., 20/20; O.S., 20/100. There was a large contraction in the superior visual field corresponding to the angioma.

Destruction of the angioma with diathermy, using the Walker pins, was done on September 6, 1944, at the Memphis Eye and Ear Hospital. Essentially the same technique as that described in a previous case report* was used. A large retinal detachment developed, probably due to holes made in the retina with the pins. The detachment gradually became worse; so on September 26, 1944, an operation was performed with the hope of reattaching the separated retina. Following this, the vitreous was hazy for a long time which prevented a clear view of the fundus.

The patient was sent home about four weeks later with pin-hole spectacles. Iodides, internally, and the passage of time gradually cleared the vitreous so that the fundus could be clearly seen. When last

examined, February 18, 1946, her vision was 20/30 and J2. Extensive scarring and pigmentation covered both the site of the angioma and a considerable area. The retina was completely reattached. Except for a very small central canal containing blood, the large artery was converted into fibrous tissue. The vein was much reduced in size but was still considerably larger than normal. There was no evidence of a recurrence of the angioma.

COLLEGE OF PHYSICIANS OF PHILADELPHIA

SECTION ON OPHTHALMOLOGY

March 21, 1946

DR. BURTON CHANCE, *chairman*

VASCULAR DISEASE ASSOCIATED WITH ANGIOID STREAKS OF THE RETINA AND PSEUDOXANTHOMA ELASTICUM

DR. HAROLD SCHEIE and DR. NORMAN E. FREEMAN presented three patients having angioid streaks of the retina, two of whom showed marked disturbances of peripheral circulation. These two patients also had skin changes of pseudoxanthoma elasticum. The third patient had no skin changes, but did have essential hypertension. In view of the vascular changes in the other two patients, it was thought that the hypertension showed by the third patient could have been due to similar changes in his renal arteries.

The other two patients showed diminution or absence of peripheral pulses determined by oscillometer readings. Occlusion of one or more peripheral arteries was seen in both patients. The femoral arteries of both patients were calcified and could be visualized by X-ray. Biopsy of the skin and ulnar artery of one patient revealed the classical changes of pseudo-

* Published in the *Archives of Ophthalmology*, 1943, volume 30, August, page 250.

xanthoma elasticum in the skin and unusual changes in the arteries. The elastic tissue within the arterial wall was fragmented and broken up. The lumen was occluded or nearly occluded by marked hyperplasia of the muscularis, possibly as a result of loss of elastic tissue support.

Suggestion was made that physicians having patients with the angioid streaks of the retina of pseudoxanthoma elasticum should review them from the point of view of vascular disease. Since either of these two conditions can occur as the predominant feature of this generalized elastic-tissue disease, the disturbance in the blood vessels might, in some cases, be the only or most marked manifestation. This should be kept in mind, and ophthalmoscopic examinations should be carried out in all obscure disturbances of peripheral circulation, for the condition greatly resembles Buerger's disease.

Discussion. Dr. Francis Heed Adler said that the thesis of this communication was well-founded; that is, that angioid streaks of the retina, Paget's disease, pseudoxanthoma elasticum, and some forms of peripheral vascular disease are parts of the same clinical entity, which is not as yet completely elucidated.

The pathology of the arteries is not entirely clear, as was evidenced by the fact that a number of pathologists to whom these sections were shown were somewhat puzzled by them. However, the general consensus of opinion seemed to be that they were dealing with a disease process confined to the elastic tissue of the arteries. Although it has been mentioned in the literature that such changes might be present, it seems strange that no one, until now, has made a study of the elastic-tissue changes in the arteries in these cases.

These findings tend to confirm the opinion that the pathologic condition underlying angioid streaks in the retina is

a degeneration of the elastic tissue of Bruch's membrane.

Dr. Adler concluded by saying that he was grateful for the opportunity to hear this interesting and beautifully presented work.

Dr. George F. J. Kelly asked Dr. Scheie whether he had had much to do with getting this section of artery. After all, this artery was a little patulous. When this piece was removed, was the collateral circulation sufficient to carry on? One can obtain sections of skin and of similar tissues, but obtaining a section of an artery is a bit unusual.

Dr. Frank B. Walsh said that it was interesting that pseudoxanthoma elasticum was associated with angioid streaks in all the cases described. How frequently had the essayist seen angioid streaks in the absence of changes in the skin?

Dr. Harold Schie (closing) in reply to Dr. Kelly, said that the biopsy was taken with very little hesitation because the ulnar artery was completely occluded. Microscopic evidence further justified taking the biopsy by verifying the occlusion. The wall of the artery and the tissues surrounding the artery showed newly formed and anastomotic vessels as large as the very minute residual lumen of the ulnar artery. The presence of a residual lumen was even debatable. If the artery was examined several sections higher, what seemed to be residual lumen at the lower level had shifted to one side and looked like any of the anastomotic vessels. The patient was an intelligent soldier who understood the situation when it was explained to him. He was told that he would derive no benefit from the procedure, but that, if further information could be obtained, it might possibly aid others in the future.

In answer to Dr. Adler's question: Clinical disease of the peripheral vessels has not been mentioned in the literature.

Sholz did mention absence of peripheral pulses in one patient, but apparently he considered it no further. Several references to histologic elastic-tissue degeneration in vessel walls were found as part of routine microscopic studies.

A COMPARISON OF THE OCULAR SIGNS IN CHILDREN AND ADULTS SUFFERING FROM SUBDURAL HEMATOMA

DR. FRANK B. WALSH, Baltimore (by invitation), spoke on this subject. His study was based on case records of 36 infants and 54 adults. He said that the condition occurs almost exclusively in infants or children less than two years of age and in adults over 20 years of age. Trauma is unquestionably the etiologic factor in adults. There is bulging of the fontanel in a majority of infants. Both in infants and in adults there may be absence of neurologic signs but irritability and drowsiness are commonly present. The hematoma is usually unilateral in adults and bilateral in children. The spinal fluid in infants usually contains blood or is xanthochromic; whereas, in adults it almost invariably is normal.

The ocular signs. In adult patients we have not found the incidence of papilledema as high as other observers (Dandy, King, Furlow). Retinal hemorrhage was frequently present in infants, but not in adults. Both in infants and in adults dilatation of the pupil may occur. In adults such dilatation usually is on the side of the hematoma. The sign is not as important in infants, because usually in them the lesion is bilateral. Ptosis was observed contralateral to the lesion in six of our cases. Such ptosis may be supranuclear in origin, but it may be evidence that there are multiple lesions. Conjugate deviation of the eyes away from the side of the hematoma probably is due to a lesion in the hemisphere opposite the hematoma.

Pathogenesis. A point of difference between the infant and adult brain may be important as regards differences in symptomatology in these two groups. In the infant unsupported veins enter the superior longitudinal sinus. In the adult pachionian granulations serve to bind together the dura, arachnoid, and longitudinal sinus.

Discussion. Dr. J. Parsons Schaeffer said that he would like to know how many of the subdural hematomas in the earlier ages were the result of birth injuries. He also asked a question about the variation in the size of the optic foramen through which the optic nerve passes into the orbit. When the size is roomy, it might be inferred that the subdural hemorrhage would readily pass into the dural-arachnoid interspace; when blood does not so pass, it might be considered as due to the bony encroachment on the optic nerve and its sheaths and interspaces.

Dr. Francis Heed Adler said that the high incidence of subdural hematomas in infants could be logically explained by the prevalence of birth injuries. Every normal birth exposes the child to cranial compression. When one considers that the fontanels are open at birth and for some time after birth, it is no wonder that there should be a high incidence of intracranial trauma. From the time the fontanels close, the child is not often exposed to any serious intracranial damage until he reaches the age at which serious accidents are apt to occur. In other words, the falls and bumps of the nursery do not produce intracranial pathologic conditions, but industrial accidents often do. It would seem to be much more logical to assume that this was the explanation of the distribution of subdural hematomas according to age, rather than to base an explanation on an anatomical difference between the cranial contents of the infant and the adult.

Dr. Adler said that Dr. Walsh had asked him to comment on ptosis as a sign of supranuclear paralysis. Since the lid muscles have a separate representation in the frontal cortex, it is possible to have a supranuclear paralysis by a lesion situated anywhere from the cortex on down to the nucleus. This, of course, is not true of the individual muscles controlling the movements of the eyeball. Further than this, the fiber tracts for the levator and orbicularis (this latter is questionable) run together with the fiber tracts for upward and downward movements of the eyeballs in the region of the corpora quadrigemina. Accordingly, lesions in this neighborhood cause disturbances of upward and downward movements of the eyes, together with ptosis and tucked lids. A few years ago, Collier called attention to ptosis and lid retraction as signs of supranuclear paralysis of the third nerve; thereby differentiating these lesions from those affecting the third nerve, itself, or the nucleus. If the lesion be anterior, lid retraction is apt to be present; whereas, if the lesion be posterior, ptosis occurs.

Dr. Walter I. Lillie said that Dr. Walsh was to be congratulated on his presentation of a very difficult subject, since the classification of traumatic cerebral changes is not always too well-differentiated. Clinically, it is often difficult to correlate the multiple bizarre changes with a single lesion. Although a single large lesion is present, associated small multiple lesions help to explain the syndrome. Dr. Lillie said that Dr. Walsh had not specifically explained why a subhyaloid hemorrhage occurs in infants and not in adults. The occurrence of subhyaloid hemorrhages in adults is usually associated with a compression injury to the chest or the neck, but it is possible that it may occur from intracranial venous compression.

The diagnosis of subdural hematoma is

usually supported by an encephalogram, as the variations in the fluid channels reveal the space-taking lesion.

The occurrence of general convulsions in adults should suggest a frontal, temporal, or occipital-lobe lesion. In such cases, a routine perimetric-field examination should be instituted. Many times a quadrantal homonymous hemianopsia has been found a year or two in advance of other definite signs of a space-taking lesion.

Dr. Henry A. Shenkin said that he would like to add a few remarks from the neurosurgeon's point of view. Dr. Walsh made an effort to distinguish between subdural hematoma in the child and in the adult, and it is true they are quite different. The fact that there are open fontanels in the infant would well account for the difference in symptomatology.

Papilledema does occur in adults but it has been Dr. Shenkin's experience that it rarely is seen in infants. The fact that the fontanels are open could permit sufficient expansion of the calvarium to absorb the pressure. The presence of convulsions in childhood may well be due to a lowered convulsive threshold, said to be characteristic of infancy. However, the length of time to which the cortex is subjected to irritation may be the convulsive factor. It is known that brain tumors of slow growth are the ones most frequently associated with seizures; subdural hematoma of long duration may be more frequently associated with seizures. The open fontanels, compensating for the increased mass of the hematoma, permit the child to survive for periods far in excess of the usual time in which the life of an adult would be threatened by a chronic subdural hematoma. It is likely that the subdural hematoma of infancy is caused by birth trauma. The appearance of the lesion, and the history of the child's development substantiate this. Physicians are

usually consulted when the child is 6 to 12 months of age. In the case of adults life-threatening symptoms from chronic subdural hematoma usually develop in 6 to 12 weeks after their injury.

Unilateral dilatation of the pupil is more characteristic of acute subdural hematoma than of the chronic form. Dr. Shenkin said that he believed subdural hematoma of infancy to be more analogous to the latter entity than to the former. Indeed, ipsilateral dilatation of the pupil is far more characteristic of the fulminating syndrome of acute epidural hemorrhage than of the more slowly developing acute subdural hemorrhage.

He agreed that the results of treatment of subdural hematoma of infancy are poor. This could be explained by the delay in making a proper diagnosis. The growing brain is compressed for undue periods of time, and often it never recovers sufficiently to develop to its full capacity.

Dr. J. Parsons Schaeffer said that he would like to bring out these two points. First, there is some thought that the facial nerve may, in some manner, cause the peculiar behavior of the upper eyelid in certain cases. Some of the fibers that arise from the nucleus of the oculomotor nerve descend in the medial longitudinal fasciculus and either terminate about the cells of the nucleus of the facial nerve or join the facial nerve as such, passing in the facial nerve to the upper part of the orbicularis oculi muscle; thus, associating the innervation of the levator palpebrae with that of the orbicularis oculi. Although it is generally accepted that the oculomotor supplies the levator palpebrae and the orbicularis oculi is supplied by the facial, this intermingling of the fibers of the two nerves may well be variable enough to account for such peculiar manifestations with reference to the action of the upper eyelid. Much more study needs to be done.

The second point concerns the new-born

infant to which the speaker referred. There is no doubt that the veins, as they course to enter the superior-sagittal sinus, are fairly free. It is, however, equally true that the mesothelium covering them does not add much protection. Later, in the adult, as the brain membranes become more pronounced and the interspaces are developed, the parts become matted together near the superior-sagittal sinus. Also, the arachnoid and the subarachnoid spaces in the form of arachnoidal granulations are protruded into the superior-sagittal venous sinus; the endothelium, of course, is crowded ahead. This adds further to the crowding near the venous sinus and to the encroachment upon the cerebral veins as they enter the dural sinus.

Dr. Frank B. Walsh (closing) replied to Dr. Schaeffer by saying that, in some infants, birth injury was a possible explanation for subdural hematoma but that it was extremely doubtful if this was so in a majority of infantile cases presented. They have not made studies on the optic foramina.

Dr. Adler's explanation of supranuclear ptosis involving the lid opposite the hematoma is interesting. However, there is no characteristic feature in such a ptosis that would eliminate the possibility of it having been produced by a homolateral, uncompleted, third-nerve palsy. It is well that attention was drawn to Collier's paper, which is excellent.

Dr. Walsh agreed with Dr. Lillie that there may be multiple lesions in these cases. He was unable to explain the pre-retinal hemorrhages seen in cases of subarachnoid hemorrhage. It is thought such retinal hemorrhages are venous in origin. One would think they might be associated with sudden increase in intracranial pressure. However, Gardner has shown that the intracranial pressure in many cases is not increased.

DR. THEODORE L. TERRY, *presiding*

A METHOD OF ENTOPTIC SCOTOMETRY

DR. JOSEPH L. LO-PRESTI read an interesting paper on the above subject. Dr. Lo-Presti said that the minute, constantly moving entoptic particles best seen through blue or red-blue filters may be used as test objects in central scotometry. These have been called red or white blood corpuscles but the more noncommittal term "motes" is proposed because of their small size and motion. These two features, together with their presence throughout the entire field all at the same time, make them ideal test objects. An apparatus was devised to measure and record those areas where they are absent, scotomas. This consists of a brilliant source of illumination; a 10 diopter, wide lens to achieve Maxwellian illumination in the eye; an iris diaphragm with cross hairs; a well to hold, at a distance of 190 mm. from the eye, cleared X-ray film on which scotomas are outlined by means of a soft crayon; a water cell containing a solution of saturated copper sulfate and basic fuchsin transmitting wave lengths of 350 to 470 and 550 to 620 μ ; and a chin rest.

A small, central area free of motes, the blood-free area of the fovea, is present in all normal fields. In 10 normal subjects this was found to measure from 1.2 to 2.4 mm. and was identical for both eyes. These figures agree with the average reported by Sperling, Miller, and Adler in 78 normal eyes, 1.5 mm.

To rule out extraocular factors, 10 cardinals, 3 anemics, and 2 leukemics were studied and found to have normal-size, mote-free areas. If increasing pressure is brought to bear on the eye examined, the

motes first slow down and finally stop. Using a Baillart ophthalmodynamometer, pressure readings of 80 to 120 gm. had to be exerted before the motes stopped moving in 25 normal subjects. For the 15 subjects with cardiovascular disease and blood dyscrasias, pressure readings were found within this range.

A total of 65 cases, divided into three groups, was reported: (1) those showing close correspondence with results employing the Evans method of campimetry (30 percent); (2) those showing fair correspondence (50 percent); (3) those showing poor to no correspondence (20 percent). These groups included cases of old chorioretinitis, retinitis pigmentosa, occlusion of branch of retinal artery, traumatic hole of macula, multiple sclerosis, tobacco amblyopia, juvenile and senile macular degeneration, diabetic chorioretinopathy, retinal separation, and quinine amblyopia.

Dr. Lo-Presti stated that in all cases of active disease of the posterior segment of the chorioretina a markedly reduced pressure reading was shown to obliterate motion of the motes.

EFFICIENCY OF CYCLOPLEGICS

DR. S. JUDD BEACH made some remarks regarding the efficiency of cycloplegics, in the absence of Dr. Alexander E. MacDonald who was to have been guest speaker of the evening and who was to have read a paper on "War-time Research in Ophthalmology." Dr. Beach said one factor in the contradictory pronouncements regarding the efficiency of cycloplegics is the variation in the response of different individuals rather than the different types of drugs used. Another is the unreliability of the tests for depth of cycloplegia. Three common tests are:

1. Nearpoint test, made by placing usually a +3.00D. sph. before the eye

corrected for distance. Type should then focus at 13 inches. The advantage of this method is that residual accommodation is stimulated by approaching type to eye but measurements are increasingly subject to error the nearer the type approaches the eye, and vary with the personal equation.

2. Placing test type at focal point of convex lens. Then estimate residual accommodation by noting the highest concave lens which can be overcome.

3. By retinoscopy.

Dr. Beach said further that there seemed to be no sound reason for the popular method of cycloplegia which employs atropine three times a day for three days in children; homatropine five times in an hour for young adults or scopolamine twice in an hour at any age. In general, this method does not increase the depth of cycloplegia beyond that resulting from single instillations of the same drug. Resistance to the drugs varies with individual idiosyncrasy rather than method of administration. It may even differ in the two eyes of the same person.

According to Dr. Beach, three sorts of response can be identified:

1. Complete relaxation both for near and distant vision.

2. Complete relaxation for distant vision with residual accommodation active at near.

3. Accommodation in evidence both for near and distant vision. This occurs in about 10 percent of all cases. Contrary to common belief, resistance to cycloplegia is not a property of younger ages, nor of higher astigmatic errors.

In closing, Dr. Beach said that dibotulin, a nonmydriatic cycloplegic, seems about as effective for distant vision as homatropine. Cycloplegia gives valuable information but is not as reliable as is generally believed. Mahlon T. Easton,

Recorder.

DR. HOWARD F. HILL, *presiding*

EXPERIENCE IN OPERATIONS ON THE SUPERIOR AND INFERIOR OBLIQUE

DR. CONRAD BERENS read an interesting paper on the above subject. Dr. Berens observed that during the past 20 years he has performed an increasing number of operations on the vertical acting muscles, especially on the inferior obliques. In his study of results following surgery, it became apparent to him that failure to obtain good binocular vision or functional results was caused most commonly by hyperphoria or hypertropia. He pointed out the importance of carefully observing the anatomic relationship of the attachment of the inferior oblique to the globe. In freeing the muscle from its attachment, one must be careful not to injure the optic nerve; and when re-attaching the inferior oblique, care must be taken not to puncture the inferior vortex vein. He also stressed the importance of the suspensory ligament of Lockwood and the condensation of Tenon's capsule forming the ligament between the inferior oblique and the inferior rectus muscle.

The following indications for retroplacement of the inferior oblique were outlined:

1. Moderate degree of monolateral or bilateral hypermetropia or hyperphoria caused by a paresis or paralysis of the contralateral superior rectus, with or without marked spasm of the inferior oblique.

2. Esotropia complicated by spasm of the inferior oblique, causing an upshoot of the eye as it is adducted.

3. Paresis of the superior oblique and secondary spasm of the inferior oblique of the same eye.

4. Fibrosis of the lateral rectus muscle with secondary spasm of the inferior oblique of the same eye. The average effect on 97 patients for a 1 mm. retroplacement of the inferior oblique was at 6 m., 0.9^{Δ} ; at 25 cm., 0.9^{Δ} in the primary position. In the field of action of the inferior oblique at 25 cm., the effect was 2^{Δ} . The average effect obtained by myotomy of the inferior oblique at the orbital margin was in the primary position at 6 m., 5.3^{Δ} ; at 25 cm., 7.7^{Δ} ; and in the field of action of the inferior oblique at 25 cm., 11^{Δ} .

The indications for advancement of the inferior oblique at the orbital attachment were suggested as: (1) Hypertropia associated with homolateral pseudoptosis, the result of the depressed position of the eyeball when caused by paresis of the inferior oblique. (2) Postoperative paresis of the inferior oblique, especially when cyclotropia prevents fusion. (3) Paresis of the inferior oblique associated with lateral deviations. (4) May be combined with an advancement of the superior rectus.

Dr. Berens also suggested transplantation of the superior oblique for complete third-nerve paralysis. He first corrected the heterotropia and then, if binocular function was adequate or diplopia could be disregarded, he corrected the ptosis.

In conclusion, Dr. Berens again emphasized that he had found a careful study of the oblique muscles and correction of their anomalies by surgical intervention to be one of the most important factors in obtaining good functional results in the surgery of the ocular muscles. Because the importance of the obliques has become increasingly apparent in the department of motor anomalies of the New York Eye and Ear Infirmary, he now has records of more than 700 operations which have

been performed on the inferior obliques.

SOME EXPERIMENTAL AND CLINICAL OBSERVATIONS CONCERNING STEREOPSIS

DR. HERMAN M. BURIAN read an interesting paper on the above subject. Dr. Burian said that stereopsis is a perception sui generis. It is not simply one aspect of even the highest refinement of single binocular vision. It is to some extent independent of single binocular vision, since it can be shown to exist in diplopia, where there is simultaneous binocular perception but not single binocular vision. On the other hand, stereoscopic perception may be electively suppressed. This means that single binocular vision exists only for identical images, while the disparate elements of stereoscopic pictures are suppressed. This elective suppression may be regional and limited to the central retinal area. Although stereoscopic sensitivity in normal individuals is, to some extent, a function of visual acuity in that it decreases from the center to the periphery of the retina in the same ratio as does the visual acuity, a certain independence is again shown by the function of stereopsis. Patients who suppress centrally the stereoscopic elements may have perfectly normal visual acuity; while others who have an amblyopic eye may show a surprisingly high degree of stereoscopic sensitivity.

Dr. Burian concluded by saying that this was not the time to go into the theoretical implications of the facts he had mentioned but that he believed it safe to say that stereopsis is a physiologic process; that is, stereopsis is the result of stimulation of specific central nervous arrangements by specific stimulus patterns. It is not a psychologic process, as is the fashionable belief in some circles.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to Dr. Derrick Vail, 55 East Washington Street, Chicago 2, Illinois; Society Proceeding to Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin. Manuscripts should be original copies, typed in double space, with wide margins.

Exchange copies of medical journals should be sent to Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising* 837 Carew Tower, Cincinnati 2, Ohio. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor*, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

ADVANCES IN THE CARE OF MUSCLE ANOMALIES

On a recent trip to the Middle West, discussion with a colleague brought out the comment that there was still much to be desired in the results obtained from muscle surgery. It must be admitted that at times our results are very disappointing even after detailed preoperative study.

However, a review of the change that has taken place in the care of muscle anomalies during the last 25 years shows

that, while there is still much to be learned, great advance has been made during that time.

I have recently had the occasion to go over some records of squints operated upon by my late chief 30 to 35 years ago. The "muscle workup," as measured by our present standards, was very incomplete. The child was refracted to determine the amount of the refractive error and its possible relation to the squint. The amount of squint was measured on the perimeter

and gross tests were made for the presence of ocular palsies. No prism measurements were made and very little attention was given to the difference in prism diopters, between the degree of squint for distance and near. The obliques were "holy ground" and received very little attention, the edict being that they should be left alone.

The surgery consisted of an advancement or resection of one muscle and a complete tenotomy of the opponent. The operator took pride in being able to correct the squint in one operation, irrespective of the amount, and looked upon the surgery as a failure if this was not accomplished. The effort was to obtain an immediate "cosmetically good" result. The fact that convergence might be absent or that there might be limitation of the tenotomized muscle was no deterrent. No attempt was made to give the child preoperative training in the hopes of preparing the ground for the establishment of binocular vision. Postoperatively, attempts were made to establish some form of fusion by the use of the stereoscope. Very little effort was made to improve the vision of the amblyopic squinting eye. As late as 1928, Ernst Fuchs* in discussing the amblyopic squinting eye states: "The most important argument has been over the improvement of the vision of the amblyopic eye by its use. Attempts have been made to do this by prolonged occlusion of the nonsquinting eye. The prolonged occlusion of the well eye is not practical, and the daily occlusion of the eye for an hour is useless. For this reason I long ago discarded this procedure which is still used rather extensively."

This, then, was the attitude of the average well-trained ophthalmologist of

the last generation, particularly the European-trained man.

However, in that same generation such men as Duane, Jackson, Worth, and others were doing original work on extraocular muscles which was to lay the foundation for our more modern conception. More recently this was advanced by the work of Peter, Bielschowsky, and White. A comparison of the muscle training available to our residents and that obtainable 25 to 30 years ago brings out in a rather startling manner the advances made in the interim.

Today the final goal is the establishment of third-degree fusion in every case of squint, and while this is not possible in every instance, the percentage of successful cases is much higher than that obtained by the older methods. The proper preoperative use of occlusion of the non-squinting eye, with improvement of vision in the amblyopic eye in a large percentage of the cases; the careful measurement in prism diopters of the amount of deviation in the six cardinal directions of the gaze; the preoperative use of orthoptics: all these aid in the determination of the surgical procedure indicated.

This information also makes it possible to determine in most instances whether or not fusion will be possible. Orthoptics, intelligently used, will at times indicate that it is best not to use orthoptics and occlusion, since the result would be a troublesome diplopia.

A rather significant indication of the advancement made in the care of muscle anomalies in recent years is the new attitude toward the oblique muscles. Much has been done to improve our knowledge of the action and physiology of these muscles. The methods of diagnosis of the anomalies of the obliques have also been improved. While there is at times still a good deal of debate as to whether or not the overaction of a given oblique muscle

* Fuchs, Ernst. Aus *Meiner Augenärztlichen Praxis*; Festschrift der Königl. Universitäts-Augenklinik In Zagreb, Jugoslawien, Zagreb, 1928.

is primary or secondary, the fact remains that these muscles are better understood than they were 25 years ago.

The operative procedures used in the correction of squint, in recent years, have been designed to correct the deviation safely, and to make possible the normal physiologic action of the muscles. This is borne out by the newer procedures that have been presented for the correction of anomalies of the obliques. The detailed postoperative care received by these cases is also instrumental in evaluating the newer procedures. Thus, for example, evidence is beginning to accumulate which would indicate that recession of the inferior oblique at its insertion may be a better procedure than the tenotomy of the inferior oblique which has been used. The new operations that have been presented in the last few years for anomalies involving the superior oblique further show the advancement that is being made.

It is true that there are still many debatable points regarding squint surgery, but the amount of work that is being done in this field is constantly changing our conceptions of muscle anomalies and will continue to enhance our knowledge of the diagnosis and care of this condition.

Yes, we have come a long way in the last 25 years in the care of squint cases, and the future of this field of ophthalmology looks bright.

Frederick C. Cordes

VINTAGE OPHTHALMOLOGY: NOT A FABLE

Once or oftener upon a Time, a Physician who received his M.D. in 1919 found that he possessed many of the Attributes for specializing. Being Smart he had gone through Medical School without squandering his Gray Matter on the curriculum. He married Miss Mud City of 1920, whose Father had lost no money

as Postmaster, Sheriff, Insurance Agent, and Dog Catcher. Having thus obtained What It Takes, the Doctor went away to the Polyclinic and soon learned to speak Ophthalmology (Vintage 1921) almost like a Native. In a few weeks he returned able to perform a creditable Extracapsular Lens Extraction and with a Mydriatic could fit Glasses which seldom Bounced Back. He was absent from Class the Day they studied Perimetry, but bought the first Refractoscope in the State with red and green Traffic Lights and by 1935 owned a Slit Lamp Corneal Microscope. This he exhibited at the County Medical Meeting but was heard to say privately that for most cases he could do as well with a Loupe and Oblique Illumination. This was probably Understatement, as he was found at the Board Examination with his Face in the Chin Rest, and the Patient at the Eyepiece.

He was strong for Civic Betterment and Death on the Charlatans who foist Bogus Eyeglasses on the unsuspecting Public, and did Right by those referring him Cataract Patients. He did not own a Tonometer, finding his own experienced Touch more Remunerative. Monocular Loss of Vision which did not yield to Violet Light administered over Months from a small Cyclotron to eliminate the Toxin, he found went on to Complete Blindness. Competitors, Consulted years later, often called these cases Absolute Glaucoma or Detachment of the Retina, but they, at that Stage, could do no more for them than he could. So it soon became widely said, as he was the First to Admit, that if he could not cure you No one could.

He said his most grateful Patients were those from whom he had removed an Eye, and charged them accordingly. He kept a Stud of Cadillacs, and was Director of the Mud City Institution for Savings. By the time his Income Tax had exceeded his

net Take, and his Kick-Back from the Purveyors of Glasses was in 5 Figures, he felt that the Eye Board ought to present him with a Certificate on Record, and on the possession of Diploma from Augenkliniks in Languages that he could read no better than he could understand when in Europe. He failed to see why at the Examination, Questions should be asked in the Basic Subjects. In Optics he had practised extensively for Twenty Years without knowing which Way and how much a Prism displaced an Object; in Pathology, he pointed out the Futility of wasting Time on Glaucoma, so long as the Production of the Aqueous is in Dispute; and why learn about the Relation of the Eye to General Diseases when the Patient is to be referred to an Internist anyway? If the Examiners did not know the Answers, why ask him? They could look them up just as easily as he could.

When advised to take Post Graduate Courses in certain Clinical Subjects, he replied that he was then devoting his Time to Teaching them to his Interns. Which could throw considerable Light upon a Number of Casualties which they encountered later. So when the Board explained patiently that repeating the same Mistake for Twenty Years does not qualify an Ophthalmologist for Certification, he persuaded a Delegate to the Annual Meeting to present a Resolution that the Boards should award Certificates to Ophthalmologists who had sacrificed fifteen to Twenty-five of their Best Years to the Practise of their Profession, without demanding too much detailed Knowledge of the Subjects which they had not studied during those Years. This Wording succeeded in deceiving the Gullible into the Belief that these Subjects had been Pursued during some unspecified Period with Painful and Exhaustive Diligence. His Chairman's address at the Eye and Ear Section Meeting of the

State Medical Society concerned "Use of Penicillin in Ophthalmology and Otolaryngology." It did not differ materially in Wording from Fundamental Concepts presented in the Monographs distributed gratis by the Manufacturers of Fine Pharmaceuticals, and in Fact repeated the Misprints made in their Bibliographies and References. The Resolution failed of Passage and he now maintains that it is easy to become a Household Word and put 'em through the Wringer like a Plumber without learning the Drivel required by the Boards.

MORAL: HAVE YOU TRIED 10-PERCENT D.D.T.?

S. Judd Beach.

BOOK REVIEWS

EYE MANIFESTATIONS OF INTERNAL DISEASES. By I. S. Tassman, M.D. St. Louis, C. V. Mosby Company, 1946. Second edition. Cloth-bound, 614 pages, 243 illustrations including 24 in color. Price, \$10.00.

The second edition of this book is similar in most respects to the first. For the benefit of those who did not have access to the first volume a short review of its contents may be of interest.

The first third is for the most part confined to general textbook considerations, such as the study of the anatomy, abnormalities and manifestations, and methods of examining the patient. There seems no particular reason for including these in a book with the title such as this since they are duplicated in all complete textbooks.

Beginning with page 269, the material from then on is exactly what the title implies. The method used is the presentation of a brief description of the disease to be considered, followed with the detailed account of the ophthalmic findings. These

conditions are clearly, concretely, and interestingly given.

The illustrations are satisfactory. This second edition coming so soon after the first indicates the good reception of edition one. There are 13-percent more pages in the second than in the first edition, as well as 40 new illustrations. About eight subjects not included in the first edition are now added.

It is always important to have a book of ready reference to the eye findings in general disease and this one is well-worth owning because it serves the purpose of including so much in one volume.

Lawrence T. Post.

LES ASPECT NORMAUX ET LES ANOMALIES CONGÉNITALES DU FOND DE L' OEIL. By Danis Marcelle. Report presented to the Société Française d'Ophthalmologie, August 25, 1940.

LES ASPECT PATHOLOGIQUES DU FOND DE L' OEIL DANS LES AFFECTION DE LA RÉTINE. By Gabriel Renard. Report presented at the March 25, 1946, meeting. Price, 1,000 francs.

Although these two contributions are units of a periodical which is published irregularly, it is fitting that they be given the dignity of a book review rather than be noted in the Abstract Department, for an abstract would insufficiently emphasize the scope of this undertaking. Each volume is in reality an atlas of ophthalmoscopy that covers a limited portion of the subject. Intrinsically, each is a book, and a very fine one, illustrated with beau-

tifully reproduced colored drawings of the fundus. Together they have more than 150 pages of text.

The text of the earlier volume consists of a historical introduction and a brief description of the instruments and methods of ophthalmoscopy, including the use of filters and polarized light. A review of the anatomy of the structures accessible to ophthalmoscopic inspection forms the basis for interpretation of fundus manifestations. This material with its bibliography covers 98 pages. All fundamental facts are dealt with adequately yet without the padding that so many authors dare not leave out lest they be thought unknowing. In the remaining 101 pages of the earlier volume, congenital anomalies and variations of the fundus are described systematically. Each section has numerous black and white illustrations and an extensive bibliography. The 35 colored plates are constantly referred to for illustration of the text. Each colored plate also receives a brief comment on the facing page.

The second volume, that by Renard, is an atlas of 32 excellently printed colored drawings of the fundus in a variety of pathologic states. Degenerative lesions receive most of the discussion, and pictures exhibit many entities of diverse phases. This volume covers only a small part of fundus pathology, but, since it is numbered "one," it may be presumed that the plan is to cover other lesions in future volumes. The text consists entirely of thorough descriptions and discussions of each figure with excerpts from the clinical record of the patient whose fundus was studied.

F. H. Haessler.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

CRYSTALLINE LENS

Barraquer Moner, J. I. **Intraocular air injection in cataract extraction.** Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, April, pp. 339-343.

Barraquer illustrates the behavior of air injected into the anterior chamber in eyes with and without vitreous loss, and gives precise indications for the procedure. It is useful to prevent or ameliorate the consequences of inclusion of vitreous fibers in the wound when vitreous is lost, or when a disturbed postoperative relation between the iris and the corneal section is feared. The syringe containing air is sterilized in a glass container. (12 illustrations.) Ray K. Daily.

Barraquer-Moner, J. I. **Keratotomy with pneumatic fixation in phacoeresis.** Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, June, pp. 448-456.

The author's device for making the corneal section in a cataract extraction fixes the entire cornea through a

vacuum, and cuts the limbus perpendicularly to the plane of the iris. The advantages claimed for such an incision are the adequacy of a smaller section, the accessibility of the root of the iris, and the easier introduction of corneoscleral sutures. In complicated cataract with occlusion of the pupil, the posterior synechia are separated from the lens by a spatula introduced through the peripheral iridectomy behind the iris. In occlusion of the pupil the occluding membrane after separation from the lens is perforated with the spatula and one or several small sphincterotomies made at the lower margin of the pupil. This relaxes the rigidity of the iris, and makes room for the manipulation of the suction tip and the delivery of the lens.

Ray K. Daily.

Bujadoux, A. **New method of keratotomy and its use in the operation of cataract extraction.** Arch. d'Opht., 1946, v. 6, no. 1, pp. 22-28.

Bujadoux discusses the advantages

and disadvantages of the Gräfe knife incision and the incision with keratome completed by scissors. He has designed a keratome resembling in shape the knife of Barraquer with which the incision can be made in a single motion without the use of scissors. The author's instrument is introduced into the eye at 9 o'clock for the right eye and at 2 o'clock for the left eye, a counterpuncture is made, and the movement continued until the section is completed. Good fixation of the eye is necessary and is accomplished by having the assistant control simultaneously a superior rectus suture and a fixation forceps at the insertion of the external rectus. The operator maintains fixation at 7 or 8 o'clock. The author states that if a conjunctival flap is desired it is possible to obtain one. After the keratotomy has been completed the lens can be extracted by any of the standard procedures.

Phillips Thygeson.

Cordes, F. C., and Barber, A. **Changes in lens of embryo after rubella.** *Arch. of Ophth.*, 1946, v. 36, Aug., pp. 135-140.

The eye of a 7 to 8-week embryo was obtained through a therapeutic abortion. The mother had rubella during the sixth week of pregnancy. The lens showed definite retardation of development and differentiation, whereas the posterior segment of the eye seemed normal. The author suggests that the absence of the protection of the lids and of Descemet's and Bowman's membranes during the first three months of pregnancy may permit the toxic agent in the amniotic fluid to act fairly directly on the lens during this time. The presence of these barriers after the third month may explain the absence of initial changes in the lens after that time. (2 photomicrographs.)

John C. Long.

Corrado, M. **Action of proteolytic ferments on lens substance.** *Ann. di Ottal.*, 1946, v. 73, Feb., pp. 91-113.

After summarizing the work of others on the digestive power of trypsin on normal lens substance Corrado presents his own studies of the in vitro action of trypsin on both the normal and cataractous lens. He used human lenses and those of oxen, calves, and rabbits. Sterile trypsin obtained by passage through a Berkefeld filter was used throughout.

The lens capsule was found to be impervious to trypsin. The ferment must have direct access to the lens substance in order to act upon it, and has a slightly greater digestive power on cataractous than on normal lens proteins. Corrado will report later his studies of the possible therapeutic value of trypsin, injected under the conjunctiva or into the anterior chamber, in postoperative lens remains and in traumatic cataract.

Harry K. Messenger.

Daily, R. K., and Daily, Louis. **A simple technique for the closure of cataract incisions.** *Texas St. J. Med.*, 1946, v. 42, Aug., pp. 284-286.

A conjunctival incision is made 5 mm. from the cornea and the conjunctival flap is undermined to half of the corneal circumference. The flap is reflected to expose the limbus and a 6-0 double armed black silk suture is placed 3mm. in the episclera at the limbus. Section is then made. The two sutures are then passed through the conjunctiva as close to the cornea as possible. The section is enlarged and the operation continued. The suture is tied at the end of operation. The conjunctiva flap is sutured with a running stitch. The suture is water tight. The anterior chamber reforms early. Sutures are removed on the eighth day.

I. E. Gaynon.

Del Rio, G. P. **Electric cataract.** Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, March, pp. 245-252.

An electrician, 36 years of age, was struck by a 5,000-volt current. In addition to general injuries he had enormous hematomas of the lids, with extensive conjunctival chemosis and hematoma. Several months later he developed visual impairment, and was found to have bilateral, subcapsular lenticular opacities. The cataract in the right eye progressed to a complete milky opacity, and that in the left appeared to be stationary. The right eye was operated on and normal vision was recovered. The uncertainty of the prognosis because of possible damage to the fundus, and the relation to industrial compensation is discussed. The literature is briefly reviewed.

Ray K. Daily.

Druault, M. **Suture lines of the lens and arrangement of the fibres.** Arch. d'Opht., 1946, v. 6, no. 1, pp. 16-21.

The author reviews the embryology of the lens and discusses the arrangement of the suture lines in various animals and in man. He notes that in the newborn human the lens star has three branches whereas in the adult it may have from six to nine. He describes the entopic images of the lens sutures and their significance. The article is illustrated with thirteen drawings.

Phillips Thygeson.

Garcia Miranda, A. **Bilateral cataract extraction.** Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, April, pp. 344-350.

Garcia reviews the literature. He performed six bilateral extractions, and one eye became infected because of a dacryocystitis which was overlooked. The second eye had good vision. Five patients had good binocular vision.

Ray K. Daily.

Gruber, M. **Primary familial dysplasia of the lens.** Ophthalmologica, 1945, v. 110, July-Aug., pp. 60-72.

This is the report of dominant hereditary formation of a bilateral membranous cataract in two generations of the same family. Three children of a father with this malformation of the lens had the same condition. After reviewing the literature and the various theories on the subject the author stresses the possibility of a primary dysplasia of the epithelium of the lens. He doubts that an intrauterine iritis is the cause of the membrane. Surgery is often difficult owing to the toughness of the membrane and an optical iridectomy may often yield better results than a forced discision or removal of the whole membrane with loss of vitreous.

Max Hirschfelder.

Haro, E. S. **Hereditary disk-shaped (ring) cataract.** Arch. of Ophth., 1946, v. 35, July, pp. 82-100.

The disk-shaped, or ring, cataract is a rare form of congenital cataract that has been reported relatively few times. The hereditary tendency has been reported in only one family. In July, 1944, a 10-year-old girl with congenital disk-shaped cataracts was brought to the eye clinic of Stanford University Hospital. Her history led to the study of a family, of 59 persons, of whom 16 have the same congenital anomaly.

All the members examined presented the type of cataract known as "disk-shaped," or "ring," characterized by the absence of the lens nucleus. This is due either to a failure of development of the primary fibers (Collins) or to a secondary resorption of the central parts, following an idiokinetic disturbance at an early stage (von Szily). This suggests the presence of genes controlling the development of the

nucleus. Apparently, such genes are dominant.

Association of these cataracts with ectopia lentis was found in all the patients examined. No other local or systemic anomaly was present. (5 illustrations, references.) R. W. Danielson.

Johnstone, I. L. Heat ray cataract. Trans. Ophth. Soc. U. Kingdom, 1944, v. 64, pp. 252-256.

Ten cases of heat ray cataract are reported. The author emphasizes the clinical findings. With a +12 lens in the ophthalmoscope one quickly sees the discrete posterior lens opacity silhouetted against the fundus reflex. With the use of the slitlamp the changes in the anterior lens capsule, the brassy reflex, and the granular appearance of the posterior cortex could be seen. Beulah Cushman.

Knüsel, O. The morphology of an electric cataract. Ophthalmologica, 1946, v. 111, April-May, p. 298.

The disturbance of vision occurred one year after injury with a high voltage current (18,000 Volts). He describes the morphologic characteristics of the cataract, and differentiates it from senile cataract and the cataracts of tetany and myotonia.

Alice R. Deutsch.

Meisner, W. Intracapsular and extracapsular cataract extraction. Revue Bulgare d'Opht., 1943, v. 2, pp. 129-136.

The results of the extracapsular cataract extractions are not greatly inferior to those of intracapsular extractions. The latter are more difficult, there is greater danger of vitreous loss, secondary hemorrhages and late detachment of the retina; the slight postoperative reaction is an advantage of the latter method.

Alice R. Deutsch.

Moreu, Angel. Postoperative hyphemia in cataract extraction. Arch. de la Soc. Off. Hisp.-Amer., 1945, v. 5, June, pp. 467-471.

After a brief reference to the role of trauma in this complication, the author dwells in detail on the ocular metabolism of vitamin C. Experimental toxic or traumatic cataract in dogs in associated with a significant reduction of vitamin C in the aqueous, and an increase in its oxide. The stimulation of the orthosympathetic system by injections of acetylcholine or doryl into the anterior chamber led to the appearance of ascorbic acid in the aqueous. The atropinization of the eye was followed by its disappearance. After extracapsular extraction the vitamin C content of the aqueous is reduced; in intracapsular extraction it is entirely eliminated. These findings may explain the greater incidence of hyphema after intracapsular extraction. On the basis of the experimental data relative to the vitamin C content of the eyes. Moreu urges that the ortho-sympathetic system be stimulated preoperatively, and that massive doses of vitamin C be administered preoperatively, and for ten days postoperatively. Atropine should not be used, and dilatation of the pupil should be obtained through the use of sympathetic stimulants, such as concentrated epinephrine. Ray K. Daily.

Munoz, J. A. Congenital zonular cataract, tetanic cataract, and rickets. Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, March, pp. 253-264.

The literature is reviewed and a family reported, in which the father, five sons; and one daughter had zonular cataracts; the mother and two daughters had normal eyes. All the affected children had dental defects; only one had bony deformities in the hands, which could be attributed to rickets.

One child with normal eyes had chorea. The illustrations show that the form of the opacities was somewhat different in each case, but all were situated in the embryonal and fetal nuclei. Of the seven patients, two were emmetropic, three hypermetropic and two myopic. The anteroposterior axis of the lenses was not shortened; the blood calcium was normal. During a four-year period of observation the opacities were stationary. As the tabulated data show, these cataracts could not be attributed to tetany. The dental defects suggest rickets as the possible etiology probably because of a calcium deficiency in the mother. (2 illustrations, 1 table.)

Samuels, Bernard. Proliferation of lens epithelium. *Amer. Jour. Ophth.*, 1947, v. 30, Jan., pp. 1-11. (1 color plate, 28 figures, references.)

Schmid, A. E. A contribution to the knowledge of contusion and massage cataract: permanent and transitory types. *Ophthalmologica*, 1946, v. 111, June, pp. 365-371.

The author describes the eyes of a patient with bilateral congenital ectopia lentis. The lens in the right eye was luxated into the anterior chamber and caused considerable increase in tension. The anterior surface of the lens was in contact with the posterior corneal surface and was the site of superficial transitory opacities which were temporarily increased when a needling was tried. The opacities had characteristic marginal indentations and changed their shape or disappeared whenever the lens-cornea contact was interrupted. The localization of the opacities in either the lens capsule itself or the epithelium was very difficult. The author compares the opacities with Vogt's disseminated subepithelial glau-

comatous cataract which is similar in shape but different in localization. This cataract is also a permanent opacity.

The morphologic picture of contusion cataract and of a special type of cataract after massage are similar and characterized by concave marginal indentations. The localization depends on the degree of pressure. According to the strength of the pressure it produces an opacity that is superficial and transient or deep and permanent. (References.)

Alice R. Deutsch.

Schmid, A. E. Light reflexes in spherophakia. *Ophthalmologica*, 1946, v. 111, June, pp. 359-364.

The author describes his own experimental and clinical studies on the origin and nature of the complex light reflexes that occur in spherophakia and microphakia. His patient had a luxation of the lens into the anterior chamber in her right eye and a subluxation of the lens into the vitreous in her left eye. The light reflexes could be observed in different positions of the lens. Whenever the focused pencil of light of the slitlamp reached the lens-equator under a certain angle a small semicircle of light originated on the posterior surface of the lens. In the optimal angle of incidence of the beam a part of the beam was reflected under the surface of the lens back to the point of entrance so that a ring of light encircled the whole lens. This is the phenomenon of total and continuous reflection along the border planes. A colored plate and diagrams elucidate the appearance and origin of these rather complex phenomena. (6 figures, references.)

Alice R. Deutsch.

Smith, D. P. Iridencleisis—a modification. *Brit. Jour. Ophth.*, 1946, v. 30, Oct., pp. 589-590.

On a patient 80 years of age with bilateral chronic glaucoma and cataract and with minimal vision in the better eye, an iridencleisis was done and later a cataract extraction. The first operation was modified so that the subsequent one would not derange the filtering scar. The keratome incision was made about 5 mm. above the limbus and only one iris pillar was incarcerated. The area was covered by a sliding flap of conjunctiva. The cataract extraction was successful and visual acuity was $\frac{5}{8}$. Morris Kaplan.

RETINA AND VITREOUS

Ammann, E. Heredity of hemeralopia hereditaria and tapeto-retinal degeneration. *Ophthalmologica*, 1946, v. 112, Aug., pp. 78-87.

A genealogic tree in which 53 blood relatives in five generations and 38 relatives by marriage are charted is described and analyzed. The inheritance in all four generations was direct. There was no interrupted line. Manifestly sound fathers and mothers never had afflicted offspring. The propagation of the disease through afflicted mothers is questionable. The younger offspring in an afflicted family were normal. (1 family tree, references.) F. Nelson.

Appelmans, M. M. Angiomatosis of the retina in the child. *Bull. Acad. roy. de med. de Belgique*, 1945, v. 10, no. 3, pp. 91-119.

The author reviews the history of angiomatosis and reports his observations on the eye of a child, four years of age. He observed the evolution of the disease from the stage of amaurotic cat's eye until enucleation became necessary two years later. He also describes histologic preparations from the

eye. (9 photomicrographs and extensive bibliography.) Jose Saenz Canales.

Arjona, J. The syndrome of Groenblad and Strandberg. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, March, pp. 277-290.

An extensive review of the literature accompanies this report of three cases of angioid streaks and pseudoxanthoma elasticum in women. Most of the patients with this syndrome are men. One of the three patients, 49 years of age, had retinal hemorrhages as well; which caused considerable reduction in visual acuity. The other two patients were sisters, who came because of a mild conjunctivitis; their skin lesions led to the discovery of the syndrome. Their fundus lesions were slight, and vision was unimpaired. (3 illustrations.) Ray K. Daily.

Arruga, H. The fundus of the new-born. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Oct., pp. 835-839.

Arruga points out the importance of familiarity with the appearance of the fundus of the new-born, in order not to make erroneous diagnosis and prognosis. Retinal hemorrhages are frequent in the new-born; they occur during parturition and are always absorbed within a few weeks, without leaving traces. The optic disc may appear grayish white, with hazy borders, suggestive of a mild optic neuritis. This appearance is due to the delayed retrogression of myelin, which impregnates the nerve fibers at the level of the lamina cribrosa. At 10 or 12 months of age the optic disc assumes a normal appearance. (5 colored fundus drawings.) Ray K. Daily.

Arruga, H. Detachment of the retina. *Arch. of Ophth.*, 1946, v. 36, Nov., pp. 531-536.

This is a "must" article for those interested in retinal detachment surgery. Every sentence is significant. A few outstanding statements follow.

Gonin's demonstration that retinal detachment is cured by sealing the retinal tears clarified and oriented the previously vague conceptions of the etiology, pathogenesis, and therapy of this process.

Detailed studies of the ocular fundus and histologic examinations of enucleated eyeballs have demonstrated that in idiopathic detachment the retina is much altered. It is strange that retinal detachment is not of more frequent occurrence. In histologic studies, atrophic and degenerative lesions reduce the thickness of the retina to one-third normal. In 18 years Arruga has observed more than 40 cases of retinal holes without detachment.

In order that the retina may become detached, the margins of the tear must be inverted slightly toward the interior of the eye, so that the vitreous strikes against them with movements of the eyeball.

The retina does not become detached if it is adherent to the choroid as well as to the framework of the vitreous. For this reason, chronic and degenerative processes are more likely to predispose to retinal detachment than are intense chorioretinal inflammatory processes.

Trauma as the determinate cause of retinal detachment does not have the important role which has been conceded to it in the past. Retinas do not become detached unless they are diseased, except after extensive traumatism. More frequent causes are a blow on the cranium, a fall on the heels, sneezing, coughing and, above all, excessive stooping.

The fundamental concept of the

movements of the eyes as the factor which initiates and increases the detachment is becoming more definite, but the varieties of its evolution show that other factors are also important. One known factor of influence is the size of the retinal rent. When the tear is small, there is rapid resorption of the subretinal fluid; when the hole is large, resorption is slow. The rapid formation of large tears indicates extreme friability of the retina or the existence of extensive adhesions between retina and vitreous, which render treatment ineffective. The factor of time, which used to be considered of such importance and which enhanced the urgency of operation, is being disregarded. The urgency in most cases does not lie in surgical intervention so much as in the need for bandaging the patient's eyes and enforcing relative repose.

Another of the factors which has most influence on the evolution of the retinal detachment and on its cure is the condition of the choroid. A detachment which is replaced with rest has a good prognosis, for the choroid is demonstrated to be in good condition for reabsorption. The vitreous acts as a foreign body on the choroid, which is finally destroyed. For this reason, all retinal detachments of more than two years' duration are accompanied by complete atrophy of the choroid. Consequently it is advisable to localize the diathermic action as much as possible. A thorough study of the fundus is necessary so as to avoid lavish use of diathermy over an extensive area. Immediate repetition of the operation is advisable only when tears appear which were not reached by the preceding diathermic action. R. W. Danielson.

Azcoaga, J. M. Retinal arterial tension in general hypertension. *Arch. de*

la Soc. Oft. Hisp.-Amer., 1945, v. 5, July, pp. 519-557.

The author presents a detailed physiologic study of the retinal circulation. He uses the Bailliant's ophthalmodynamometer. The study of the retinal arterial pressure is very useful in determining the stage of development of general hypertension. The retinal circulation is under greater pressure than would be suspected from the sphygmomanometric reading. The fundus picture does not necessarily correspond to the type of hypertension; since plethoric patients show consistently fewer changes, two types of hypertension, red and pale, must be distinguished. Renal and essential malignant hypertension cannot be differentiated. (14 illustrations.) J. W. McKinney.

Bailliant, P. Lectures on the vascular pathology of the retina. Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, Oct., pp. 898-911.

This is a condensed summary of Bailliant's lectures. Emphasis is placed on the fact that the retina is an extension of the brain, and the retinal blood vessels are subject to the same regulations as the cerebral vessels. The examination of vascular retinal pressures is described and the value of ocular capilloroscopy to the internist and the neurosurgeon made clear.

The etiology of arterial hypertension, and its ocular symptoms are discussed in detail; among the early symptoms are cloudiness of vision, and the need for increased illumination for near work. The fundus at this time shows edematous areas in the form of striae or points, arteriovenous compression, and punctate obliteration of some of the capillaries. If the retinal arterial tension is higher than half the brachial pressure, it is indicative of parietal

hypertension; if it is lower, it indicates obstruction below the level of the retinal vessels; in either case it means a disturbance in the cerebral circulation, and a disparity between the retinal and humeral pressures is a poor prognostic sign. Hypertension without these retinal changes is relatively benign, and is well tolerated.

For a clinical prognosis the examiner should note hyaline degeneration, capillary failure, the state of the conjunctival vessels, the results of entoscopic examination, and the state of the arterial retinohumeral pressures. A retinal arterial tension higher than half the brachial indicates retinal angiospasm, and also cerebral and renal angiospasm. A retinal arterial tension lower than normal indicates failing cerebral circulation, and such patients are apt to suffer hemianopsia or hemiplegia, even in the absence of obvious cardiac or renal changes.

In malignant hypertension, which the ophthalmologist encounters in one percent of cases, and which is due to capillary inadequacy the first signs are arteriovenous compression, followed by hemorrhages and edema at the posterior pole. Particularly grave are those which set in with thrombosis of the central retinal vein. It is really a collapse of the venous walls, rather than a true thrombosis. Retinal degeneration follows, with profound macular changes due to a disturbance in the choriocapillaries. Such changes in the retina indicate that similar processes are taking place in the higher cerebral centers. Ray K. Daily.

Bailliant, P. The retinal capillaries. Revue Bulgare d'Ophth., 1943, v. 2, pp. 34-43.

The anatomy of the retinal capillaries is described. They are ophthal-

moscopically invisible but can be examined by means of the capillaroscopy of Fortin and the endoptoscopy of Scherer. He discusses these methods in detail and stresses their importance for a better understanding of the retinal capillaries in health and disease.

Alice R. Deutsch.

Bischler, V. Pigmentary retinitis following measles. *Confinia Neur. Basek*, 1944-45, v. 6, no. 5, pp. 270-277.

The author reviews the literature and adds a case of pigmentary retinitis following measles. The condition is rare and may occur with any exanthemata. Sudden amaurosis occurs about the fourth to eleventh day of measles and is followed by slight recovery of vision. There is attenuation of the retinal blood vessels, and the fundus picture may resemble that of embolus of the central artery of the retina. The tapetoretinal degeneration appears several months or years after the acute condition. The retina may have scattered masses of pigment, a fine pigmentation, and small yellowish-white spots. At first it is progressive, then remains stationary, in contrast to the slow progression to blindness of retinitis pigmentosa.

Orwyn H. Ellis.

Bishay, A. Quinine amblyopia. *Brit. Jour. Ophth.*, 1946, v. 30, May, pp. 281-287.

The author presents seven cases of quinine amblyopia after reviewing the theories of its etiology. The two predominant theories are a direct toxic effect on retinal cells and an anemia of the retina caused by extreme constriction of retinal vessels due to the quinine. The author concludes that whatever else is involved, a personal sensitivity to quinine must certainly be a factor. In his treatment, large doses of strychnine and paracentesis were em-

ployed with better than average results. (4 diagrams.)

Morris Kaplan.

Brückner, A. The X-ray treatment of the retinoblastomas. *Revue Bulgare d'Ophth.*, 1943, v. 2, pp. 55-63.

A child, 15 months of age, is described who had advanced bilateral retinoblastoma. After the enucleation of the worse eye the other was given intermittent doses of X rays. After temporary regression of the tumor, there was a massive recurrence, secondary glaucoma, and orbital metastasis.

Alice R. Deutsch.

Ciotola, Guido. Further observations on heparin treatment of thrombosis of the central vein of the retina. *Boll. d'Ocul.* 1945, v. 24, Jan.-March, pp. 35-51.

In addition to the report published in the January 1941 issue of this periodical on a new treatment of this form of thrombosis by heparin the author now reports 35 more cases. A short history is given of each. The age of the patients ranged from 36 to 78 years. The thrombosis was total in 16 patients. The treatment was started from 2 to 90 days after the onset of the disease and the duration of treatment was 10 days, rarely longer. In five patients the vision remained stationary and in the others it deteriorated. A re-examination of 21 patients after one year showed still better vision in nine and further deterioration in five. The fundus examination showed a partial absorption of hemorrhages. The rapid improvement of vision during the treatment was due to a reduction of retinal edema as a result of the improved venous circulation. The treatment caused no secondary disturbance other than a transient rise of temperature in a few patients.

Melchior Lombardo.

Cornet, E. **Retinopexies.** *Ann. d'Ocul.*, 1946, v. 179, Feb., pp. 112-118.

Retinopexies are surgical procedures for relief of retinal detachment. They produce an adhesive chorioretinitis limited to the zone surrounding tears or generalized detachments; and affect vitreous pressure. Surgical treatment should occlude small tears, include the entire zone involved, and exclude the extension of the detachment. Because of its simplicity and uniformity in producing solid cicatrices, galvano-cautery is preferred to diathermy. Cauterization of the vortex veins will result in severe hemorrhage. Retro-retinal cystic degeneration may be primary or secondary and is more frequent than is usually believed. It occurs in 50 percent of retinal detachments in patients under the age of 40 years. Destruction of the cyst is considered essential for the permanent cure of detachments. If pockets of suprachoroidal fluid exist far from a tear, a supplementary perforating puncture is made in the affected area. For hypotension subconjunctival injections of 1/1000 solution of mercury cyanide in 5 to 10-percent sodium chloride solution is used. If the vitreous is retracted scleral resection should be considered. In detachments with tears, Gonin's operation or one of its modifications is advised. In generalized detachments the operations of Weve-Sichel, or de Wecker-Soudielle are preferred. The author's nonperforating sclerocyclectomy for vitreous retraction includes an annular excision of a 2 to 3-mm. band of sclera near the ora serrata with corresponding resection of the anterior ocular muscles.

Chas A. Bahn.

Dominguez, D. D., and Girones, E. A. **Recurrent edema of the macula.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Jan., pp. 38-54.

An exhaustive review of the literature, and a report of four cases are presented. The author believes in the identity of this affection with that described by Horniker as chorioretinitis centralis serosa. It is probably as frequent in Europe as in Japan, and the diagnosis is often missed because of inadequate attention to the subjective symptoms, and of failure to make a detailed examination of the macular region. Etiologically it is similar to angioneurotic edema, perhaps allergic in origin. In spite of the frequent recurrences the prognosis is favorable. (2 illustrations.)

Ray K. Daily.

Esente, Ivan. **Diabetic retinosis, simple and complicated.** *Riv. di Oftalm.*, 1946, v. 1, April, pp. 249-277.

In addition to an extensive review of the literature, the author discusses his own observations that suggest the clinical importance of distinguishing between the ophthalmoscopic and pathogenetic characteristics of "simple" and of "complicated" diabetic retinosis. Neurohormonal disturbances, probably originating in the hypophysis, may initiate simple diabetic retinosis in the absence of hypertension as well as hyperazotemia. Therapeutic indications may be derived from this ophthalmoscopic differential-diagnostic clue.

K. W. Ascher.

Falcone, G. A case of juvenile disciform macular degeneration. *Indian Med. Gazette*, 1946, v. 81, June-July, pp. 241-242.

This non-inflammatory disease occurs during the second and third decade of life and tends to resolve in a few months. The exudative mass has degenerative rather than inflammatory characteristics. Coats' disease, tubercle, and malignant melanoma are to be differentiated from it. In the author's pa-

tient, a European male, aged 29 years, the disease affected one eye and later the other and healed completely.

F. M. Crage.

François, J. Treatment of thrombosis of the retinal veins by heparin. *Bull. de la Soc. Belge d'Ophth.*, 1945, no. 82, Nov. 25, pp. 19-23.

The author discusses the formation of thrombosis in the retinal veins after trauma or inflammation, and believes that the use of heparin in these cases is justifiable. Heparin is the principal anticoagulant of the animal organism and since it inhibits thrombin formation, it is indicated in these cases.

Heparin was given to 17 patients; the thrombosis was located in the central vein in 12 of these and in five was located in one of the branches. For a period of 10 consecutive days heparin is injected intravenously every six hours. Eighty milligrams are given for two to three days, then 50 milligrams until a total of two grams is given.

A complete cure resulted in seven of these patients whose clinical records are presented in detail.

M. R. Cholst.

Gordon-Napier, G. An electrolysis apparatus devised for retinal detachments. *Brit. Jour. Ophth.*, 1946, v. 30, Aug., pp. 478-485.

The author describes the trials of procuring the parts and assembling an electrolysis machine in India during the war. The equipment was make-shift and the needles were ordinary sewing needles but the finished product served well for three years. Of 24 detached retinas, 12 were attached successfully at first operation, 4 after a second operation, and 8 remained defective. (4 diagrams.)

Morris Kaplan.

Gruber, M. Histologic findings in the fundus in Fahr's nephrosclerosis. *Ophthalmologica*, 1944, v. 107, Jan.-Feb., pp. 87-90.

The vessels of the choroid in Fahr's nephrosclerosis are similar to those of the kidneys. There are thickening of the intima and media and very few inflammatory processes. There were excrescences of the pigment epithelium protruding into the rod and cone layer of the retina.

Max Hirschfelder.

Hagedoorn, A. Instrument for locating retinal ruptures during operation. *Arch. of Ophth.*, 1946, v. 36, Aug., pp. 225-226.

This instrument is designed for the scleral transillumination of the globe. A minute light is enclosed in a metal tube which is affixed to the globe by teeth. A metal wing is attached to the tube to aid in manipulation and as an indicator of the position of the light. It is used in the same manner as the Goldmann instrument. The author describes its use in the localization of retinal tears and of scleral foreign bodies. (2 illustrations.)

John C. Long.

Halbron, P., and Rozan, A. Five cases of macular lesions of undetermined etiology. *Ann. d'Ocul.*, 1946, v. 179, March, pp. 131-137.

Five patients with vision from 20/40 to 20/20 had irregularity of macular pigment, diminution of macular reflex, and slight retinal opacity as the only pathologic findings. Practically all had had nutritional deficiencies as prisoners of war. None had received direct injuries.

Chas A. Bahn.

Hall, G. S. The ocular manifestations of tuberous sclerosis. *Quart. J. Med.*, 1946, v. 15, July, pp. 209-220.

Frequent ocular manifestations of

tuberous sclerosis are retinal nodules (phakomata) of which there are two types. In one type small, greyish-white, single or multiple nodules occur in any part of the retina; in the other type a large mass usually develops in the region of the optic disc, projects into the vitreous, is frequently cystic, and may produce optic nerve atrophy. The nodules are usually avascular and may be associated with alterations in the blood vessels. The lesions are composed almost entirely of glial cells, and primitive fibers. There is a whorl-like arrangement of cells with brush-like areas of gliosis. Cystic degeneration may or may not be present. The lesion can become a true blastoma.

Rarely nodules may occur in the lens and cause opacity. Histologic findings in such an eye after post-mortem are presented.

Orwyn H. Ellis.

Krause, A. C., and Sibley, J. A. **Metabolism of the retina.** *Arch. of Ophth.*, 1946, v. 36, Sept., pp. 328-348.

This monograph on the metabolism of the retina discusses the subjects under the headings of hydrogen-ion concentration, organic phosphate, oxidation-reduction potential, respiration and glycolysis, anoxia, general metabolism, respiratory quotient, fat metabolism, formation of ammonia, glycogen, carbon dioxide anhydrase, acetylcholine, and detached retina.

R. W. Danielson.

Lemoine, Albert N., Jr. **Retinoblastoma.** *Amer. Jour. Ophth.*, 1947, v. 30, Jan., pp. 52-55.

Lipkina A. I. **Tissue therapy of retinitis pigmentosa.** *Oftal. Jour. (Odessa)*, 1946, pt. 2, pp. 29-33.

Verbitskaia reported favorable results in 77.3 percent of 110 patients

treated according to the Filatov method which consists of intramuscular injections of cod liver oil, subconjunctival implantation of placental tissue, subcutaneous implantation of placenta and preserved skin. In this study the procedures used were subcutaneous injections of a specially prepared extract of leaves of aloes, kept on ice in darkness for 15 days; implantations of preserved and autoclaved cadaver and animal skin; and a combination of the two procedures.

Of the 30 patients in this study 22 were under observation less than six months, and four for one year. Almost all of them had advanced lesions. Sixteen patients were treated with an aqueous extract of leaves of aloes. The favorable effect of therapy was manifested by an increased visual acuity, extended visual field, improved reading ability, and improved dark adaptation. Only one patient was unimproved. In one patient vision rose from imperfect light projection to 0.1, and in the other from 0.01 in each eye to 0.3 and 0.2. Thus, a patient with total visual disability recovered the ability to work, read, and write. This experience justifies the assumption that the improvement would be even greater if treatment were applied early. Two tables give brief summaries of the treatment.

Ray K. Daily.

Longhena, Luisa. **Light perception in detached retinas.** *Riv. di Oftalm.*, 1946, v. 1, April, pp. 225-244.

Painstaking study of dark adaptation was performed on twenty patients suffering from retinal detachment. Campimetry at reduced illumination was also done using a perimeter of long radius and white, red, and green targets. For the adaptation test, Birch Hirschfeld's instrument was used.

After exposure to bright light for ten minutes, the eye was tested every three minutes during a period of forty minutes. In nine of the patients operation seemed to be contraindicated and in one a spontaneous recovery of the detachment occurred. Ten eyes were operated on and in seven of these there was complete restitution. One showed some postoperative improvement, one relapsed, and one became worse after the surgical intervention. Three weeks after the operation no adaptation was present in the detached parts of the retinas. It returned, however, if surgical or spontaneous recovery occurred. It took a varying period of months to redevelop. It is important to stress that the retinal pigment layer probably plays the main role in dark adaptation. In spite of the fact that it is in physical contact with the reattached inner retinal layers, it does not start to function immediately. A certain period of time is necessary to overcome an unknown organic or functional disturbance of the pigmented retinal epithelium.

K. W. Ascher.

Maggiore, Luigi. The functional relations between the pigment epithelium and the neuroepithelium of the retina. *Revue Bulgare d'Opht.*, 1943, v. 2, pp. 113-128.

This paper represents a detailed clinical, pathological, biochemical and physiological study of the importance of close contact between the pigment epithelium and the neuroepithelium for the maintenance of perfect visual function, especially, in relation to various forms of retinal detachment.

Alice R. Deutsch.

Matas, B. C. Retinitis punctata albens. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, March, pp. 269-276.

The case reported occurred in a 30-year-old man with inadequate dark adaptation since childhood. He had no consanguineous antecedents. Ten of his 19 siblings were living, and all had a history of the same disturbance, which, however, disappeared when they reached the age of twenty years. The patient noted a progressive impairment of vision during the last three years, with increasing difficulty in reading, particularly of red or blue letters. The fundi contained disseminated white points, particularly numerous at the posterior pole. The foveal reflex was absent in both eyes. There were no pigment changes. Vision was reduced to 1/10. The fields were normal. The literature on the subject is briefly reviewed, and the need for therapeutic research is emphasized. (Visual fields.)

Ray K. Daily.

Mosquera, Sanchez. Two cases of retinal disinsertion. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Sept., pp. 803-805.

Sanchez reports two cases of slowly developing retinal disinsertion in young men, in good general condition; the patients were not myopic and there was no history of trauma or infection. The vitreous, the ciliary body, and the lens showed none of the changes frequently found in old retinal detachments. Both were cured by diathermy coagulation. The slow evolution of retinal disinsertion is explained by the fact that the vitreous does not seep through as easily when there are no retinal holes and disinsertions usually occur in eyes with healthy vitreous. The organic integrity of the eye accounts for the better prognosis. This type of disinsertion with a characteristic clinical course is attributed by the author to cystic degeneration of the retinal periphery caused by embryologic malformation or consecu-

tive to an intraretinal hemorrhage that occurred during gestation or as a result of obstetric trauma. (4 illustrations.)

Ray K. Daily.

Nastri, Francesco. Further researches on pathogenesis of diabetic retinitis. *Boll. d'Ocul.*, 1945, v. 24, Jan.-March, pp. 19-34.

The writer studied the behavior of vitamins A and K in the blood of patients affected by this retinal lesion and came to the conclusion that in these cases hepatic disfunction must not be excluded from consideration. (Bibliography.)

Melchiorre Lombardo.

Pickard, R. The perioptic atrophic ring. *Brit. Jour. Ophth.*, 1946, v. 30, Aug., pp. 437-445.

These atrophic rings that are occasionally seen around the optic disc are frequently associated with glaucoma, cavernous atrophy, and retinal sclerosis. The study was made on 826 consecutive patients over 50 years of age. Most of the patients exhibited unmistakable narrowing of the retinal vessels in almost direct ratio to the amount of the atrophy. The author assumes that this narrowing is primarily found in the vessels of the circle of Zinn. (4 tables.)

Morris Kaplan.

Pines, N. Diagnostic and clinical value of some forms of retinal angiospasm. *Brit. Jour. Ophth.*, 1946, v. 30, Aug., pp. 470-476.

Painstaking exploration of the retinal arteries in the red-free light of a Wolf ophthalmoscope sometimes reveals local constrictions of the lumen. The significance of this local angiospasm only becomes clear when the findings are correlated with careful oscillometric studies of the vessels of the arms and legs. It will be found that they are an

index of the state of general angiospasm and of some value in prognosis.

Morris Kaplan.

Rubino, A. Retinal detachment with disinsertion due to a large intraretinal cyst. *Riv. di Oftalm.*, 1946, v. 1, March, pp. 149-155.

Weve distinguishes three kinds of retinal cysts: those without a retinal detachment, those secondary to a detachment, and those causing a retinal detachment. A case of the latter type is described. A man, aged 38 years, had an extensive retinal detachment involving the temporal lower retinal quadrant of his left eye with a disinsertion extending along the periphery from the 4-o'clock to the 7-o'clock position. In the lower nasal quadrant, the convex border of an enormous retinal cyst was visible two disc diameters from the papilla; its distal border was invisible. Operation consisted of transcleral diathermy coagulation; a double barrier coagulation was performed along the disinsertion, and finally, the cyst was evacuated by perforating diathermy. Reattachment of the retina and collapse of the cyst became permanent. Final vision was 0.1 because of a small central field defect whereas the peripheral field was only slightly constricted in the nasal upper quadrant. A pigment line indicated the outlines of the collapsed cyst. The author advocates the use of the perforating type of operation only in cases characterized by large retinal cysts.

K. W. Ascher.

Schneider, R. W., Lewis, L. A., and McCullagh, E. P. Plasma proteins. I. Alteration in diabetic retinitis. *Am. J. M. Sc.*, 1946, v. 212, Oct., pp. 462-465.

Clinical and biochemical studies were made in 31 cases of diabetic retinitis to determine a relationship between cer-

tain alterations in the plasma proteins and retinal changes and to determine whether a high intake of protein would change either or both of these disorders.

In inadequately treated diabetes mellitus one frequently finds typical changes that consist of a reduced level of albumin and an increase in B globulin. The total protein may be normal or slightly reduced. Unless such complications as infection, renal insufficiency, or particularly retinitis exist, the plasma protein level can be restored to normal. Where renal disease accompanies the retinitis, the plasma protein abnormalities can not always be corrected.

The diabetic retinitis in the male patients was not recognized until diabetes had been present from 12 to 25 years and in women in from 2.5 to 22 years. Four patients showed improvement. In two of them practically all the form and color field defects disappeared in a few months. Subjective visual improvement occurred in two patients. The greatest improvement in retinal changes occurred in those in whom the high protein intake restored the plasma protein to normal. High protein diabetic diets are valuable as an adjunct in the prevention and treatment of diabetic retinitis. Francis M. Crage.

Stallard, H. B. Retinal detachment due to war trauma. *Brit. Jour. Ophth.*, 1946, v. 30, July, pp. 419-429.

An analysis of 96 cases of retinal detachment that occurred in a field force is made; of these only 20 resulted from war injuries. Most of these 20 had serious ocular wounds and retained foreign bodies as well as the retinal separation. In one eye in which the retina was separated in three quadrants without a tear spontaneous reat-

tachment occurred and the vision became normal. A second less extensive detachment also healed spontaneously. Seventeen eyes were operated upon, 11 successfully. (3 illustrations.)

Morris Kaplan.

Stallard, H. B. Bilateral symmetrical cystic detachment of the retina. *Brit. Jour. Ophth.*, 1946, v. 30, Sept., pp. 547-548.

Two young patients presented almost identical bilateral, symmetrical, cystic, retinal detachments, all in the upper temporal quadrant. All were symptomless and were discovered during routine examination. All eyes were otherwise perfectly normal. One retina became reattached spontaneously and the others were operated upon by a single application of surface diathermy followed by a single puncture with the diathermy needle. Postoperative recovery was uneventful and complete. (2 illustrations.) Morris Kaplan.

Streiff, E. B. The modification of the retinal arterial tension in different positions of the body and head. *Revue Bulgare d'Ophth.*, 1943, v. 2, pp. 151-156.

The retinal arterial blood pressure does not change with the position of the head and body under normal conditions but does so in retinal hypertension and hypotension. Alice R. Deutsch.

Wagner, H. Changes in the fundus in Fahr's nephrosclerosis. *Ophthalmologica*, 1944, v. 107, Jan.-Feb., pp. 83-86.

Malignant nephrosclerosis is usually characterized by a severe arteriolosclerosis with necrosis and endarteritis obliterans in the kidneys. It is the end result, when the purely vascular "red" hypertension changes to the "white" toxic hypertension due to the disturbed

kidney function. Clinically it is characterized by intracranial pressure, insufficiency of the kidneys, vascular hypertension (especially the diastolic pressure), loss of weight, uremia, and fundus changes. Fahr distinguishes a still more fulminant nephrosclerosis from the classical picture described above. It affects younger people, is extremely malignant, and is based on exogenous, toxic and infectious influences. One finds necrotic and endarteritic processes in the kidneys similar to the periarteritis nodosa of Kussmaul. The author hopes that ophthalmoscopy may make the differential diagnosis possible which otherwise can only be assumed. He found, aside from the usual ophthalmoscopic findings of malignant hypertension, unusual pigment spots, partly surrounded by a small white area in patients who were later found to have Fahr's nephrosclerosis. Although he is not certain that the finding is constant, he believes it to be an important one. (2 photographs.)

Max Hirschfelder.

Weber, E. The anterior barrier of the vitreous. The spontaneous detachment of its lenticular plica in senility—a new slitlamp diagnosis. *Ophthalmologica*, 1944, v. 107, Jan.-Feb., pp. 108-115.

The author distinguishes a free plica of the vitreous lamella (in the region of the zonula) from that part of the anterior vitreous which covers the posterior surface of the lens as a so called "lenticular plica." Ordinarily, it is impossible to see it with the slit lamp. In young people it is rather firmly adherent to the lens itself and only the strong force of serious injuries will lead to its partial detachment. A different situation is found in people of advanced age. In such people a mild trauma may produce a total detachment of the len-

ticular plica of the anterior vitreous. Myopia also predisposes to such a condition. The fact that this plica is much more easily detachable in elderly persons explains the relative ease of intracapsular extraction in such persons as compared with the same method applied to young patients. (14 illustrations, partly colored.)

Max Hirschfelder.

Weekers, R. The role of light in the pathogenesis of essential detachment of the retina. *Bull. de la Soc. Belge d'Ophth.*, 1945, no. 82, Nov. 25, pp. 29-34.

Cases of detachment of the retina were studied for a period of 15 years at the University Clinic at Liège. Retinal detachments secondary to neoplasm, inflammation, operation, or trauma were disregarded. There were 208 idiopathic detachments. In the majority, predisposing factors such as myopia and arteriosclerosis, with or without hypertension, were found. A graph is presented which reveals an increase in the frequency of affection from March to July and a decrease from July to February. The summer and spring revealed an incidence of 31 percent and 30 percent respectively, which decreased to 21 percent in the autumn and 18 percent in the winter.

The author feels that strong light could produce a tear in a retina predisposed by arteriosclerosis or myopic choroiditis. He believes that the problem could be studied experimentally in a dog with renal ischemia and hypertension (Goldblatt kidney) by exposing the eye of such a dog to strong light.

Weekers urges the use of tinted and dark glasses during the sunny periods of the year as a prophylactic measure for predisposed individuals.

11

OPTIC NERVE AND TOXIC
AMBLYOPIAS

Alm, Inguar. Primary tumors of the optic nerve and their relation to Recklinghausen's disease. *Acta Pediat.*, 1945, v. 32, no. 3-4, pp. 262-269.

The author presents two cases of primary tumor of the optic nerve in children and discusses the relationship between Recklinghausen's disease and primary tumors of the optic nerve. He supports the view that neurofibromatosis is a disease of nerve cells and axis cylinders and secondarily causes proliferation of the surrounding supporting and protective tissues. The family of one of the patients exhibited manifestation of neurofibromatosis in three successive generations. The other patient had a primary tumor of the optic nerve and neurofibromatosis of the hip. (12 figures.) I. E. Gaynon.

Dell'acqua, G., and Poppi, U. Neuro-myelitis optica. *Riv. Oto-Neuro-Oft.*, 1942, v. 19, no. 1, pp. 1-21.

A woman, 20 years of age, with an acute paraplegia, hypoesthesia from the axillas down, bilateral choked discs and central scotoma died two months after onset of her disease, from bronchopneumonia. The lower part of the thoracic and the upper part of the lumbar spinal cord showed complete destruction of the nervous tissue. Above and below this region, disseminated lesions of demyelination, necrosis, but no proliferation of neuroglia or périvascular infiltration were found. Secondary degeneration of Goll's column was present, the brain and cerebellum were free, and the optic nerves, when stained with Weigert's solution, showed paleness of their marginal fascicles, pial thickening, and an increased number of nuclei in the interfascicular tissue.

Thus, an acute medullary necrosis was associated with an optic neuritis. The lesions had a different clinical course and a very different pathologic explanation. The combination should not, in the opinion of the authors, be considered a definite clinical syndrome. (11 figures.) K. W. Ascher.

Diez, M. A. Acute epidemic papillitis. *La Semana Méd.*, 1946, v. 53, Sept., pp. 509-534.

The author describes six cases that occurred in children. The record is intended to supplement ten cases reported by Carrillo in a paper read before the First Pan-American Congress of Neurology, Montevideo, 1944. It is suggested that these cases are the expression of acute arachnoiditis possibly due to a neurovirus. (26 illustrations, including visual fields and poorly printed fundus photographs.)

W. H. Crisp.

Freeman, J. D. J. Quinine amblyopia. *Brit. Jour. Ophth.*, 1946, v. 30, June, pp. 345-349.

A woman, 27 years of age, who had been given 120 grains of quinine because of malaria began to complain of deafness and black and green spots before her eyes. No more of the drug was given but in six days she began to complain of blurred vision which progressed to complete blindness in two more days. The pupils were large and fixed, the retinal arteries were constricted, the disc margins blurred, and there was one large retinal hemorrhage. Without specific treatment the vision very slowly returned to normal except for a slight defect in the lower portion of the field in each eye.

Morris Kaplan.

Garcia Miranda, A. Inverted Foster-

Kennedy syndrome. *Ophthalmologica*, 1946, v. 112, Aug., pp. 72-77.

A patient is described who had temporal atrophy of the disc and central scotoma in the left eye and papillary edema with normal vision in the right. A frontal meningioma situated in the right premotor region had displaced the ventricular system in a direction diametrically opposite to the tumor and had pressed the brain against the contralateral optic nerve. This rare condition, only described once before, may be called an inverted Foster-Kennedy syndrome. (2 figures.) F. Nelson.

Guha, G. S. A case of quinine amblyopia. *Indian Med. Gazette*, 1946, v. 81, June-July, pp. 238-241.

A robust Hindu, aged 28 years, complained of tinnitus quickly followed by deafness and loss of vision after the administration of 60 grains of quinine for malaria within a period of 24 hours. The vision was reduced to light perception. The pupils were dilated and fixed, the discs very pale, the retinal arteries threadlike, and the fields were very markedly contracted. Treatment included amyl nitrite inhalations, belladonna, lumbar puncture, corneal paracentesis, and vitamins. Paracentesis gave greatest relief. The vision returned to normal but some peripheral scotoma remained. (Fields, charts.)

F. M. Cragg.

Humblet, M. and Weekers, R. The diagnosis of tobacco amblyopia. *Bull. de la Soc. Belge d'Opht.*, 1945, no. 82, Nov. 25, pp. 53-64.

The authors have noted an increase of 3.4 percent in the incidence of tobacco amblyopia in the period of the war years, 1940-1945, compared to the period from 1930-1940. Among the 66 cases studied during the later period,

certain findings were noted. The affection was bilateral and the defects were symmetrical. The scotomas were centrocecal and not pericentral. The scotomas were best found with smaller test objects. The visual defect was much greater for a red test object than for a blue test object of the same size. Occasionally the centrocecal scotomas were perceived by the patients themselves as black spots. A very careful examination is required when tobacco amblyopia exists in conjunction with other ophthalmic conditions, such as, immature cataract, senile macular degeneration, and high myopia with choroiditis. M. R. Cholst.

✓ Koverzhenko, A. C. Fifty cases of retrobulbar neuritis caused by methyl alcohol poisoning. *Oftal. Jour.* (Odessa), 1946, pt. 2, pp. 38-42.

The following are conclusions based on clinical experience with fifty patients. The end result of methyl alcohol poisoning depends on the promptness of therapy. Repeated venesections followed by blood transfusions, and intravenous injections of normal salt, and glucose solutions are most effective. Lumbar punctures should be performed repeatedly during the first week. In the second week therapy should be directed towards arresting the incipient atrophy of the optic nerves, and should consist of hot baths and retrobulbar injections of atropine and strychnine. Inhalations of amyl nitrite twice daily for 15 days are of value early in the disease but later they are ineffective. Vitamin B should be used. The prognosis is poor when the initial loss of vision remains without improvement for a long time. Patients with optic atrophy caused by methyl alcohol should remain under ophthalmologic observation for a long time.

Improvement of the peripheral field has followed energetic therapy in patients treated two months after the ingestion of methyl alcohol.

Ray K. Daily.

- ✓ Moore, D. F. Nutritional retrobulbar neuritis. *Lancet*, 1946, v. 2, Aug. 17, pp. 246-248.

Retrobulbar neuritis has been one of the most common nutritional diseases in prisoners-of-war and internees in the Far East. The most outstanding deficiencies were those of the vitamin-B complex. Thiamine, though it could cure and prevent beriberi, could neither prevent nor cure the neuritis. Decreased visual acuity is the most common complaint, and partial optic atrophy the commonest fundus finding. Because of the variation, the term "nutritional optic neuropathy" is used. Marmite and dried brewers yeast, were used therapeutically and were effective if used early and in large doses. The neuritis can be differentiated from beriberi, though it can be associated with it. (3 figures, references.)

Bennett W. Muir.

- ✓ Morone, Giuglio. A typical craniofacial dystocia associated with atrophy of the optic nerve. *Arch. di Ottal*, 1946, v. 50, March-April, pp. 45-73.

Morone describes one case of Crouzon's disease, with bilateral optic atrophy. The signs were typical except that the strabismus in this patient was convergent and not divergent. Many other associated lesions have been reported: chorioretinitis, increased tortuosity of vessels, retinitis, pigmentosa, retinitis proliferans, and congenital cataract. The one common ocular finding is the optic atrophy, usually of a gray-green color, dilated sinu-

ous veins, narrowed arteries, and occasionally perivascularitis.

Morone accepts the theory that the basic disturbance is in the lymphatic tissue of the rhinopharynx, in an endocrine imbalance, and in the teratomatous development described by Crouzon. He discards all other theories. The increased intracranial pressure, which is the cause of the many complications must be reduced. Repeated lumbar punctures are purely palliative. Cranial decompression has given good results when done early.

- Seidenari, Renato. Leucosarcoma of papilla in a luetic patient. *Boll. d'Ocul.*, 1945, v. 24, April-June, pp. 152-162.

A man, 58 years of age, who for about a year had noticed a progressive diminution of vision of his right eye had a visual acuity of 1/100, negative transillumination and normal intraocular tension. The fundus examination revealed a round grayish mass occupying the entire region of the disc and protruding into the vitreous for 3 mm. A previous examination had shown a positive Wassermann reaction but anti-luetic treatment had not affected the mass in any way. A diagnosis of neoplasm of the disc was made and the eye was enucleated. The mass had not

extended backward through the lamina cribosa but appeared to have invaded the choroid. It proved to be a leucosarcoma. (Bibliography, 5 figures.)

Weekers, L. The pathogenesis of nicotine-alcohol optic neuritis. *Revue Bulgare d'Ophth.*, 1943, v. 2, pp. 161-166.

Three factors influence the course of a toxic retrobulbar neuritis. The impairment of the general health, caused by an insufficient diet, the toxic effect of the nicotine, and alcohol which lowers the general and local resistance and sensitizes the nerve elements to the effect of nicotine.

Alice R. Deutsch.

White, J. P., and Lowenstein, A. Unpigmented primary tumor of the optic disc. *Brit. Jour. Ophth.*, 1946, v. 30, May, pp. 253-260.

For two and a half years the authors observed a growing, nonpigmented tumor of the disc in a boy nine years of age. They considered the tumor a blastoma or a phakoma and since these could not be differentiated entirely from glioma, the eye was removed. The tumor consisted of a mass of foamy cells which had infiltrated the surrounding retina and had caused a cavernous degeneration of the optic nerve. Their final diagnosis was phakoma, which is a malformation developing from those undifferentiated neuroectodermal cells that are normally destined to become glial or ganglionic cells. (7 illustrations.)

Morris Kaplan.

Wright, E. J. Nutritional optic neuropathy. *Lancet*, 1946, v. 2, Sept. 14, pp. 401-402.

The syndrome of epithelial and nervous lesions complicated by nutri-

tional optic neuropathy was first recognized by H. Strachan in 1897. Multiple neuritis, trophic scattered skin lesions, and neuritis of the special sense nerves were described. Wright named vitamin A and D deficiency as the cause in 1927. Clark in 1936 concluded that cyanogenic foodstuff, a common factor in the diet of all sufferers of pellagra and allied nutritional diseases, produced a slow prussic acid poisoning. Hobbs and Forbes in 1946 suggested the prophylactic value of first-class protein; which contains much sulphur, as an antidote for cyanogenic food. The author describes his sulphur therapy in this syndrome. Francis M. Crage.

VISUAL TRACTS AND CENTERS

André-Van Leeuwen, Maria. **Clinical manifestations of pupillotonia.** *Ophthalmologica*, 1946, v. 111, June, pp. 339-350.

To investigate the hereditary background of four patients with tonic pupils, one with a tonic pupil after internal ophthalmoplegia, and another with a complete Adie's syndrome the author individually examined 63 persons.

There were no other cases of pupillotonia or areflexia in any other member of the families of the afflicted persons but there was a comparatively frequent incidence of hippus, anisocoria, slowing of the accommodation—convergence reflex, and changes in the form of the pupil. Congenital hereditary afflictions of the nervous system were entirely absent. There were many angioneurotic manifestations. Three family members and two afflicted persons who were more than 45 years of age had signs of herpes zoster, a coincidence also noticed by other investigators. (References.)

Alice R. Deutsch.

Franceschetti, A. and Bischler, V. Pharmacodynamic effects on the pupillotonia and accommodotonia in Adie's symptom. *Revue Bulgare d'Ophth.*, 1943, v. 2, pp. 85-89.

Mecholyl in 2.5-percent solution which does not change the size of a normal pupil, causes contraction of the pupillotonic pupil in a remarkable way and diminishes the latent period of accommodation. Prostigmine causes temporary impairment of the pupillary function and of accommodation. Daily doses of quinine improved the accommodation.

Studies of these reactions in two patients are described. The possible connection of the pupillotonia with the myasthenia gravis and myotonic dystrophy are discussed.

Alice R. Deutsch.

García Miranda, A. A reversed Foster-Kennedy syndrome. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Sept., pp. 737-742.

Two cases of frontal lobe tumor with chocked disc on the side of the tumor, and a central scotoma on the opposite side are reported. Ventrilography showed contralateral distension of the ventricles, which explains the compression of the optic nerve. The central scotoma on the side of the tumor is explained by the greater vulnerability of the papillo-macular bundle. (2 illustrations.)

Ray K. Daily.

Garcia Ochoa, R., and Etchemendy, A. N. Atypical Adie's Syndrome. *Anal. Argent. Oft.*, 1945, v. 6, Oct.-Nov.-Dec., pp. 133-143.

A man, 41 years of age, is presented who had a primary syphilitic lesion some years ago, and whose blood serum reactions are negative at present. Vision was normal in each eye as were

the motor status and fundi. A definite anisocoria was present, with the right pupil larger than the left. The pupil did not react to mild light stimuli, but after a latent period reacted slowly and forcefully to light, even after it had been removed. Kneejerks were absent. A complete discussion of the literature is given. The diagnosis must differentiate this lesion from myelitis, meningitis, arteriosclerosis, syringomyelia, and tertiary syphilis. The disease is benign. (Bibliography.) Edward Saskin.

Lodge, W. O. Bitemporal hemianopia. *Brit. Jour. Ophth.*, 1946, v. 30, May, pp. 276-281.

Brief case reports of three patients with pituitary tumors and bitemporal hemianopia are presented. All three were operated upon with immediate good results though two died of recurrence. (2 colored plates.)

Longhena, L., and D'Ajutolo, F. Opticochiasmatic arachnoiditis. *Riv. Oto-Neuro-Oft.*, 1946, v. 21, Jan.-Feb., pp. 1-42.

The writers report a clinical and surgical study of ten cases of opticochiasmatic arachnoiditis in which surgery was done in the eye department of the University of Bologna. The diagnosis is based almost exclusively on the ocular symptoms: the reduction of vision, the changes in the visual fields, and the changes in the fundus. Under local anesthesia craniotomy by the right transfrontal route was performed and the optic nerves and the chiasm were freed of pathologic adhesions. The ages of the patients ranged from 18 to 54 years. Seven patients were males. The Wassermann reaction was positive in one, symptoms of tuberculosis of the lungs were present in an-

other, nasal and paranasal symptoms were present in two, and chronic alcoholism in one patient. In six patients there was good and permanent improvement, in two the ocular condition remained stationary and two died. The outcome is most favorable in recent inflammations and in those of slow evolution. Neuro-surgical therapy is the treatment of choice. Medical treatment was of no avail. (Bibliography and 20 figures.) Melchior Lombardo.

Love, J. G., and Rucker, C. W. Recovery from blindness following removal of suprasellar epidermoid. Proc. Staff Mtgs. Mayo Clinic, 1946, v. 21, May 15, p. 193.

A man, forty-five years of age, presented himself with complete blindness in the left eye. There were only two nasal islands of vision in the visual field of the right eye. Despite the absence of roentgenographic confirmation, a craniotomy was performed and a suprasellar epidermoid cyst was removed. A surprising recovery of vision took place, and after three years, the visual acuity had increased to 6/30 and 6/6, although there was persistent bitemporal hemianopsia. Benjamin Milder.

Mazzini-Rizzo, Ercole. Two cases of opticochiasmatic arachnoiditis treated surgically. Riv. Oto.-Neuro.-Oft., 1942, v. 19, no. 1, pp. 22-48.

One of these extensively studied patients had been suffering from a syphilitic opticochiasmatic arachnoiditis. In the other differential diagnosis was somewhat difficult because of signs of intracranial tumor. In both, surgery confirmed the diagnosis of opticochiasmatic arachnoiditis. In the syphilitic patient one eye became blind in spite of surgery and intensive antiluetic treatment. The other patient retained

some vision in both eyes for four years. Preservation of vision can only be expected if surgery is performed at an early stage. (7 figures.)

K. W. Ascher.

Pendergrass, E. P., and Perryman, C. R. Opticochiasmatic arachnoiditis. Am. J. Roent., 1946, v. 56, Sept., pp. 279-298.

Opticochiasmatic arachnoiditis produces a syndrome similar to that produced by a tumor in the region of the optic chiasm. It may result from syphilitic meningitis, mastoiditis, sinusitis, petrositis, chronic rhinopharyngitis, encephalitis, multiple sclerosis, and tuberculosis. The arachnoid is thickened, grayish, opalescent, and may contain cysts. The optic nerves and chiasm are atrophic and are usually enmeshed in adhesions. Patients complain of loss of vision in one or both eyes and headache that is usually frontal. The optic discs may be normal, but more often are atrophic and ten percent of patients have papilledema. Central scotoma, concentric contraction and temporal loss are the most common field defects. Diagnosis is made by air encephalography. Ten cases are reported. (24 figures.) I. E. Gaynon.

Seidenari, Renato. Craniopharyngioma in an adult patient with a choked disc. Riv. Oto.-Neuro.-Oft., 1941, v. 18, no. 4, pp. 293-299.

A 26-year-old female patient developed a central scotoma for white and for colors in the right eye and a relative central scotoma and a complete temporal paracentral hemianopic scotoma in the left. Ophthalmoscopy revealed a choked disc in the right eye and a postneuritic optic nerve atrophy in the left. A suprasellar tumor was diagnosed after ventriculography, and

surgery resulted in removal of a suprasellar prechiasmic craniopharyngioma.

E. W. Ascher.

Whitten, R. H. Scotoma as a complication of decompression sickness. *Arch. of Ophth.*, 1946, v. 36, Aug., pp. 220-224.

Forty-one medical students were exposed a total of 100 times to lowered barometric pressure in a decompression chamber that was equivalent to ascents to simulated altitudes of 35,000 and 38,000 feet (10,600 to 11,500 meters). Pure oxygen was supplied for altitudes above 10,000 feet (3,000 meters). Twenty-eight men on 37 ascents suffered from decompression sickness. Ten men on 18 of 34 ascents manifested various visual symptoms or headaches. Five men on 7 of 11 ascents manifested scotomas. The scotomas were of a bilateral homonymous, incongruous type with macular sparing, peripheral drifting, and continuity across the vertical midline. Identification of the causative lesion is not at present possible.

EYEBALL AND ORBIT

Brognoli, Carlo. Intermittent exophthalmos, probably from a sympathetic lesion simulating the picture of angioneurotic edema of Quincke. *Arch. di Ottal.*, 1946, v. 50, March-April, pp. 74-96.

Brognoli describes and discusses in great detail the experience of a woman, 20 years of age, who had recurrent edema of the lids and exophthalmos for several months. The lids of the right eye had a non-inflammatory, non-pitting edema and the eye was displaced moderately forward and slightly laterally. Ocular motility was normal.

There was no pulsation or bruit. In the fundus there was edema of the disc and retina, dilatation and tortuosity of the vessels, and no hemorrhage. The left eye was externally normal and there was slight edema of the nasal border of the optic disc. Vision was 0.2 and 0.7 in the right and left eye respectively.

About the twenty-fourth day after admission the patient developed severe headache and later became irrational and convulsive. Because of obstructed breathing a rhinologic examination was done and hypertrophy of the right middle turbinate was noted. The turbinate was removed. Within three days the edema and the exophthalmos had disappeared. The fundus and the vision slowly returned to normal. The symptoms had not recurred after four months.

Brognoli believes that the middle turbinate stimulated branches of the sphenopalatine ganglion.

Brown, A., and Harper, R. K. Craniofacial dystosis; the significance of ocular hypertelorism. *Quart. J. Med.*, 1946, v. 15, July, pp. 171-182.

The author differentiates the chief types of craniofacial dystosis. Among them hypertelorism is a deformity associated with undue separation of the orbits. It is present in infancy, persists throughout life, and is usually bilateral. Mental defects may be present. Patients usually have strabismus and defective visual fields. Binocular vision is considerably impaired for near. The history and literature is reviewed and the author presents two families in which the condition was present in three generations. Orwyn H. Ellis.

Capus, B. *Clostridium welchii* pan-

ophthalmitis. Arch. of Ophth., 1946, v. 36, Aug., pp. 226-228.

A soldier was injured by the explosion of a wooden land mine that produced lacerations of the face and a puncture wound of the left eye. He was promptly given penicillin and sulfadiazine. In spite of this medication the eye became immobile, proptosed and extremely tender. There was no light perception. Pressure on the cornea resulted in a gush of coffee-colored exudate and gas with a characteristic odor. Evisceration was performed, and within the liquefied necrotic contents was found an irregular piece of wood. The same coffee-colored exudate was found in the facial wounds. Smears and cultures from the eye revealed a gram-positive bacillus with all the cultural and morphologic characteristics of *Clostridium welchii*. All signs of systemic effects of the toxin ceased after the patient was given 180,000 units of tetanus-gas gangrene antitoxin intravenously.

John C. Long.

Cristini, Giuseppe. Ocular changes in experimental hypoglycemia.. Riv. di Oftalm., 1946, v. 1, March, pp. 156-179.

Five female guinea pigs, weighing between 600 and 800 grams each, were used for insulin experiments. They received doses ranging between 40 and 200 units and a total of 400 to 2,000 units of insuline. The blood sugar values after observation of two to fifteen convulsions, were 0.70 to 0.35. The method used for blood sugar determination was that of Crecelius and Seifert. During the hypoglycemic attacks the pupils were markedly dilated and failed to react to strong light. Intraocular pressure decreased during these attacks and became very low before the animals died. The corneal microscope revealed no changes of the

corneas nor of the anterior chambers although a slight hyperemia of the iris vessels was obvious. About two hours after the administration of the drug, a slight opacification of the anterior suture lines of the lens was noticed. High-power biomicroscopy showed finest striation originating at right angles from the suture lines. At this stage the lenses appeared opalescent; with progressing intoxication, they assumed a milky appearance which showed some regression when, after glucose administration, the animals were brought back to normal blood sugar levels. Small cortical opacities that developed later on between the anterior discontinuity zones, proved to be irreversible after glucose administration. In one of the animals, a transient change of the anterior lens grain was observed. If the animals succumbed, they were used for histologic examinations. Vascular as well as parenchymatous changes were observed in the organs and severe retinal, choroidal, and optic nerve affections were encountered. The possible mechanism of the pathogenesis of these alterations and those of the lens is discussed. The lenticular changes seem to result from anoxia. (Bibliography.)

De Leonibus, F. Histologic study of the ocular and orbital metastases of the transplantable malignant lymphosarcoma of fowls. Ann. di Ottal. 1946, v. 73, April, pp. 207-216.

This tumor, discovered by Pentimalli and described by him in 1940, has many resemblances to lymphatic leukemia and sarcomas. When inoculated in the pectoral muscles of fowls there is metastatic dissemination and proliferation of the cells in the orbital and ocular tissues. The lacrimal gland was a favored site for massive infiltration. Transplants

thrive in the anterior chamber and spread through the sclerocorneal trabecula along the arteries and veins to the subconjunctival tissue and invade the vascular tunic of the globe.

Harry K. Messenger.

García Miranda, A. **Fibroma of the orbit.** Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, Sept., pp. 759-767.

The literature is reviewed and a fibroma in the left orbit of a 25-year-old man is reported. The tumor was extirpated and recovery was uneventful. (4 photographs, 2 microphotographs.)

Ray K. Daily.

Goldmann, H. **Reconstruction of a socket for prosthesis.** (Höhlenplastik.) Ophthalmologica, 1944, v. 107, Jan. Feb., p. 60.

After removal of all conjunctival remnants and dissection of the skin and external canthus to the bony margin of the orbit an impression of the socket is made with pliable "Kerr Masse." A Thiersch flap from the thigh is wrapped around this moulage and put in place. Adaptation of the lids follows. The external canthus is reconstructed in a second operation, one week later, followed by the reconstruction of the fold of the upper lid (ptosis operation after Elschmig).

Max Hirschfelder.

Jona, Sergio. **Direct and indirect orbital fractures radiating into the optic canal.** Riv. Oto-Neuro-Oft., 1942, v. 19, no. 1, pp. 49-69.

Among seven meticulously observed patients suffering from either direct or indirect fractures of the bony orbit, none showed any fifth nerve lesion, amazingly few extraocular muscle involvement, and only one had enophthalmos. In five patients, a descending

optic nerve atrophy occurred, causing total irreparable blindness; two remaining patients developed hemianopia. The author considers severe contusion of the nerves to be responsible for the pathogenesis of the nerve lesions. In patients with initially well preserved visual function, later formation of a bony callus may cause a final loss of vision. (Six X-ray photographs, bibliography.)

K. W. Ascher.

Kalfa, S. F. **A case of pulsating traumatic enophthalmos.** Oftal. Jour. (Odessa), 1946, pt. 2, pp. 15-18.

Kalfa reports a case of fracture of the orbit with separation of the fragments in the superior external portion of the orbit that resulted in pulsating enophthalmos and ptosis. There was no aneurismal bruit or dilatation of the ocular veins. The pulsation of the eyeball was very pronounced and was synchronous with the pulse. The enophthalmos is attributed to the separation of the fragments in the superior orbital wall and a recession of the orbital fat towards the cranium. The pulsation is believed to result from transmission of the pulsation of the brain through the defect in the orbit. Tenotomy of the four rectus muscles was without effect on the enophthalmos.

Marin Amat, M. and Marin Enciso, M. **Colobomatous cyst and microphthalmos.** Arch. de la Soc. Oft. Hisp.-Amer., 1945, v. 5, July, pp. 566-578.

One more case of colobomatous cyst and microphthalmos is added to the literature of ophthalmologic teratology. It occurred in an infant, twelve days of age, whose left eye was normal. A detailed anatomic study of the malformation is reported. (7 illustrations.)

J. W. McKinney.

Massoud, F. **Proptosis-differential diagnosis.** *Brit. Jour. Ophth.*, 1946, v. 30, Oct., pp. 622-630.

For purposes of differential diagnosis, cases of proptosis are divided into six categories. 1. Apparent—as in myopia and buphthalmos. 2. Congenital anomaly—as in shallow orbit and cranial hernia. 3. Trauma—as in cavernous sinus thrombosis and arteriovenous aneurism. 4. Inflammatory process. 5. New growths. 6. Systemic conditions—as in hyperthyroidism and hyperplastic blood dyscrasias. The author presents eight case reports very briefly.

Morris Kaplan.

Ortin, L. G. **Orbital hemorrhages in early infancy.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, March, pp. 227-237.

Two cases of large subperiosteal hemorrhage in the outer portion of the orbit, in infants under two years of age are reported. There was a vague history of trauma in each and both recovered completely under large doses of vitamin C. A vitamin C deficiency is the probable etiology.

Ray K. Daily.

Sédan, Guiral, and Reinhard. **Sebaceous orbital cyst associated with a large lacuna of the craniofacial skeleton that suggested a meningocele or even an encephalomeningocele.** *Ophthalmologica*, 1946, v. 112, Aug., pp. 57-62.

In 1934, Sédan observed a small nasoörbital meningocele with a very large gap in the skull. The X-ray picture appeared in the radiological Atlas of Hartmann. The author, in collaboration with Guiral and Reinhard saw a second, radiologically identical case with a genuine nasoörbital hole, in a

little girl with a congenital orbital sebaceous cyst, not of a dermoidal character. Its removal was successful.

Despite the different nature of the conditions two X-ray pictures were identical. (2 X-ray plates.)

F. Nelson.

Tolosa, E., and Gospert de Ignacio. **Fronto-orbital multiocular cyst, lined with respiratory mucous membrane.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Oct., pp. 840-855.

A case of mucocele of the right frontoethmoidal sinus extending into the cranium in a woman, 45 years of age, is reported. The ocular symptoms were unilateral exophthalmos, displacement of the eyeball down and out, and involvement of the first, second, and third cranial nerves on the diseased side. The patient also had symptoms of increased intracranial pressure, and epileptiform attacks. The radiographic studies were suggestive of a dermoid. The neoplasm was extirpated through craniotomy and was found to consist of a multilocular mucocele, lined with respiratory mucous membrane and filled with a sterile mucopurulent material. The literature on mucoceles extending into the cranium is reviewed.

EYELIDS AND LACRIMAL APPARATUS

Arruga, H. **The form of lacrimal probes.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Nov., pp. 943-948.

After a criticism of the lacrimal probes in use, Arruga describes his probes, which are bayonet-shaped, and similar to the Ziegler probes, except

that their lower end is 22 mm. instead of 35 mm. long. These do not impinge on the superciliary ridge, and do not press on the bone. (8 illustrations.)

Ray K. Daily.

Bangerter, A. **Contribution to the diagnosis and therapy of lacrimation.** *Ophthalmologica*, 1944, v. 107, Jan.-Feb., pp. 51-54.

Systematic examination of the lacrimal canaliculus and the tear sack is indicated whenever the fluorescein test is negative. Positive irrigation of the sack after minimal introduction of the canula (just passing the tearpoint) indicates an abnormal position of the punctum or its stenosis. If it is impossible to irrigate the sack after this short introduction, an obstruction of either the canaliculus itself or of the tear-sack must be assumed. The differential diagnosis concerns the location or the type of such an obstruction and is made by passing the canula forward with a further trial of irrigation. Probing, and injections of privine, which produces shrinkage of the mucous membrane, complete the investigations. Valve formation within the canaliculus is treated with electrocoagulation and a residual probe for a few days. A stenosis of the canaliculus or the duct is sometimes cured by repeated probing with introduction of a temporary rubber band. The author recommends dacryocystorhinostomy for patients who cannot be benefited by these conservative methods. Max Hirschfelder.

Barraquer, T. **Internal fistula of the lacrimal sac.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Oct., pp. 896-897.

A three-year-old child with a phlegmon of the lacrimal sac and intense pericystitis was treated by an

incision into the lacrimal sac, evacuation of pus, and packing. In packing it was noticed that the cavity was very deep. By irrigation with mercurochrome it was demonstrated that the sac opened into the nose. When healed there was a larger lacrimonasal communication than normal.

Ray K. Daily.

Barraquer, T. The preliminary staining of the lacrimal sac in operations on the sac. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Oct., pp. 884-886.

Barraquer injects a five-percent fresh aqueous solution of methylene blue into the lacrimal sac just before extirpating it. A few moments before beginning the operation, pressure over the sac expells the dye, leaving its wall stained. Failure to do so leads to staining of the entire operative field as soon as the sac is opened. With the excess solution expelled the walls of the sac stand out in dark contrast, and total extirpation is facilitated.

Ray K. Daily.

Gonzales, J. B. Dacryostomy in industrial accidents. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Oct., pp. 887-895.

The author presents tabulated data on the results in 28 cases of extirpation of the lacrimal sac, and 48 cases of dacryocystorhinostomy, performed as a part of the therapy of traumatic corneal ulcers. The data clearly show the superiority of dacryocystorhinostomy. The final visual acuity is better and the course of the corneal infection is shortened.

Ray K. Daily.

Guellbenzu, M. D. A contribution to dacryocystorhinostomy. A continuous suture of the anterior mucous membrane flap. *Arch. de la Soc. oft. Hisp.-Amer.*, 1945, v. 5, Nov., pp. 949-964.

Anesthesia, skin incision, trepanation, and formation of the mucous membrane flaps do not differ from the customary type. For enlarging the lacrimo-nasal opening the author devised a trephine which works rapidly without danger of injuring the nasal mucosa. The posterior flap is sutured in the customary manner; the anterior flap is sutured with a continuous silk suture, which can be removed without traumatizing or disturbing the flaps. The ends of the suture come out thru the skin, on the nasal side of the incision, and a central loop is held against the nose with adhesive plaster in such a way that the anterior mucosal flap is pulled forward. (7 illustrations.)

Guyton, Jack S. A simple method of removing eyelashes by electrolysis. *Amer. Jour. Ophth.*, 1947, v. 30, Jan., pp. 57-58.

Knapp, P. Treatment of blepharoclonus with injection of alcohol. *Ophthalmologica*, 1944, v. 107, Jan.-Feb., pp. 63-66.

Severe blepharoclonus can be remedied with injections of 1 to 2 c.c. of 70-percent alcohol. The injection is preceded by local anaesthesia and 2-percent novocaine solution 15 minutes before the alcohol injection into the orbicularis muscle. Hot compresses are recommended. Usually, five to eight injections were necessary and recurrences were frequent. However, they could be suppressed by more alcohol injections. Of 26 patients 24 responded to this treatment. Most of the patients were over 60 years of age.

Max Hirschfelder.

Marin Amat, M. and Marin Enciso, M. Treatment of ectasia of the lacrimal

sac by partial resection of its anterior wall. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Aug., pp. 822-827.

The authors advocate resection of the anterior lacrimal wall with forcible dilatation of the nasolacrimal opening as a simpler procedure and just as effective as extirpation of the lacrimal sac or dacryocystorhinostomy. The sac is exposed as for dacryocystorhinostomy. After excision of the anterior wall of the dilated sac a number 5 or 6 probe is passed into the nose through the lacrimo-nasal opening. The walls of the sac are sutured with a continuous heavy silk suture, the ends of which are passed through the skin, and tied over beads. Suture of the skin incision and irrigation of the lacrimal sac to insure its permeability completes the operation. Acute infection and impermeability of the lacrimo-nasal opening are contraindications. As the last point is not predictable, the authors suggest that every surgical approach in chronic ectasia be begun as this procedure. It can be converted to an extirpation of the sac or a dacryocystorhinostomy, as the indications for these procedures become apparent during the operation.

Ray K. Daily.

Marin Enciso, M. Bilateral hysterical pseudoptosis. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, April, pp. 357-360.

Hysterical pseudoptosis is in reality not a ptosis, but a spasmodic blepharospasm. It is usually monocular; bilateral involvement is very rare. A woman, 39 years of age, with an irrelevant history, and without neuropathic antecedents in the family, developed a bilateral inability to open the eyes. There were no folds in the lids or forehead, position of the eyebrows was normal and there was resistance

to having the lids lifted by the examiner. The patient was cured by injection of novocain and alcohol into the outer canthi with the assurance of a cure. The author stresses the importance of coupling suggestion with objective therapeutic measures, to which the patient and the family may attribute the cure. A very dogmatic behavior on the part of the physician may lead to failure.

Moreu, A., and Fornes, E. A case of epithelioma of the lachrymal gland. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Jan., pp. 59-63.

A tumor of the lachrymal gland was excised and two months later it recurred at the orbital margin. Excision of the recurrent nodule was supplemented by irradiation, with no further recurrence. Histologic examination revealed an epithelioma of low malignancy. (2 microphotographs.)

Ray K. Daily.

Rintelen, F. The therapy of lachrymation. *Ophthalmologica*, 1944, v. 107, Jan. Feb., pp. 32-42.

This paper classifies the causes of lachrymation. They may be hypersecretion of the tear gland, anomalies of the position of the lids and stenosis of the lachrymal duct. The physiology of the lachrymal apparatus and the various means for correction of pathologic changes are discussed.

Max Hirschfelder.

Spaeth, E. B. Blepharoptosis. *Trans. Amer. Acad. Ophth. and Otolaryng.*, 1946, March-April, pp. 142-162.

Approximately 100 patients with blepharoptosis who were examined and treated by the author during a 20 year period are classified and analyzed surgically.

Congenital ptosis is classified as follows: 1. Unilateral ptosis without superior rectus involvement (40 percent); 2. unilateral ptosis with involvement of homolateral superior rectus (21 percent); 3. bilateral ptosis without superior rectus involvement (7 percent); 4. bilateral ptosis with bilateral superior rectus involvement (8 percent); 5. unilateral ptosis with weakness of both superior recti, but more marked in homolateral eye (2 percent); 6. ptosis with more or less complete third nerve and even with sixth nerve paralysis (9 percent); 7. ptosis with classical jaw-winking reflex (3 percent); 8. ptosis with Duane retraction syndrome (2 percent); 9. ptosis with neurofibromatosis (10 percent).

Acquired or symptomatic ptosis is etiologically and anatomically classified as follows: 1. traumatic peripheral; as in sectioning of the levator, in cicatrization, in osteomyelitis, after blepharoplasty, and after reconstruction of a socket; 2. traumatic, central and cerebrospinal; in 3rd nerve paresis or paralysis, and cervical sympathetic paralysis due to nerve section; 3. neoplastic or inflammatory peripheral; 4. atonic; senility and blepharochalasis, and after simple enucleations; 5. neuromuscular disturbances; myasthenia gravis, myasthenia of thymic tumors, ophthalmoplegias of thyrotoxicosis; 6. ptosis of cervical sympathetic involvement; Horner's syndrome; 7. ptosis of third nerve lesions; 8. ptosis with pseudo-Graefe syndrome; 9. hysterical ptosis.

Congenital ptosis in classes 1, 2, 4, and 5, and occasionally 9 is usually best corrected by a levator advancement with a partial tarsectomy. Those of class 3 are ideal for the Moutais-Parinaud technique. Ptosis in class 6 and those in 1, 2, and 4, which are accom-

panied by completely paralyzed levators is best corrected by the techniques of Gifford, Hunt-Tansley, or Reese in which fibers of the orbicularis are transplanted. In patients in class 6 extraocular muscle surgery should be done before correcting the ptosis. Those in classes 7 and 8 are corrected by tenotomy with tenectomy of the levator (resection without reattachment) and later a Reese transplant of the orbicularis fibers to the occipitofrontalis. Those in class 9 are corrected by the Hess technique.

In acquired ptosis in class 1 the levator is used if not severed. When the levator is severed, the occipitofrontalis is used. In patients in class 3 the underlying orbital condition should be corrected before correcting the ptosis. For ptosis in class 4 a levator resection with resection of the atonic skin is indicated, and the skin should be quilted to the anterior surface of the tarsal plate. Ptosis in myasthenia gravis is not a surgical problem; removal of a thymic tumor corrects the ptosis in thymic myasthenia; thyrotoxic ptosis usually requires an orbicularis transplant. In ptosis of class 6 a levator advancement by the transconjunctival route is indicated. In classes 2 and 7 surgery for oculomotor paralysis should precede the use of orbicularis or fascia lata transplants to utilize the occipitofrontalis. In class 8 a levator myectomy and tenotomy is indicated; surgery for the accompanying ocular paralyses may then be done. For ptosis of class 9 no surgery is indicated.

The occipitofrontalis, the superior rectus if normal, and the levator may be used surgically. Levator advancements demand a partially intact levator, and may be done after the second year of life. Superior rectus utilization on the Parinaud-Moutais principle, is never

done unilaterally; the Kirby and Shoemaker modifications are best. Bilateral levator or superior rectus surgery should be done on both eyes at the same time and not before the third year of life. Ptosis in infants, especially when bilateral, should be operated upon early; crutch glasses may be used beforehand. Crutch glasses are of especial service in complete external ophthalmoplegias.

A chart of the several types of ptosis and their surgical indications is presented. Charles A. Bahn, M.D.

TUMORS

Ajo, Aarni. A case of chondroma bulbi. *Brit. Jour. Ophth.*, 1946, v. 30, Aug., pp. 465-470.

A 19-year-old Finnish sailor complained of pain, redness and dimming of vision for two years in an eye in which the vision had been poor since early childhood. As long as the patient could remember he had had two tumors in the conjunctiva. Examination revealed a nearly blind eye with two discrete cylindrical tumors under the conjunctiva that extended up into the upper fornix and into the stroma of the opaque cornea. Biopsy revealed a true hyaline cartilage tumor intimately mixed with lacrimal gland tissue. Enucleation was refused but the patient returned in a year when the tumors had grown appreciably. This growth seemed malignant but surgery was again refused. (6 illustrations.)

Morris Kaplan.

Bertoldi, Maria. Adenoma of the Meibomian glands. *Rassegna Ital. d'Ottal.*, 1941, v. 10, March-April, p. 211.

A tumor was seen in the left lower lid of a 43-year-old woman two years before its complete removal. It had originally been treated as a chalazion and partially removed three times before. The histologic preparation showed a characteristic picture of an adenoma of the Meibomian glands. This benign tumor is less frequently seen than the epithelioma. (3 figures.) E. M. Blake.

Bonnet, P. A diffuse hyperplastic papillomatous tumor of the cornea, originating from an old pannus. *Revue Bulgare d'Opht.*, 1943, v. 2, pp. 44-54. (See Section 6, Cornea and sclera.)

Di Ferdinando, R. An angiomixosarcoma of the choroid arising in the stump of an exenterated globe. *Rassegna Ital. d'Ottal.*, 1941, v. 10, March-April, p. 182.

A 52-year-old woman first observed loss of sight in the right eye at the age of 16 years. Eight years later the eye was blind and troublesome and enucleation was advised and refused. After the lapse of another five years an exenteration of the globe was performed and a good motile stump resulted. No further symptoms were observed for eight years when the shrunken eye gave pain and a fungating mass gradually developed. This was removed and the histologic examination revealed an angiomixosarcoma. (9 figures.)

Sykes, E. M. Interstitial irradiation therapy in carcinoma, originating at the limbus. *Texas St. J. Med.*, 1946, v. 42, Oct., pp. 376-380.

Radon seeds were implanted between the sclera and conjunctiva and sutured into position there in patients with primary squamous celled epithelioma at the limbus. In one there has been no recurrence after five years and after one year in the other.

The radium element seed or tube is described and notes are given on how to use it on the eyeball.

Francis M. Crage.

Verzella, Mario. Malignant Neoplasms of the Meibomian Glands. *Riv. di Oftalm.*, 1946, v. 1, March, pp. 189-212.

According to Morax, only 34 cases of carcinoma of the Meibomian glands have been described since Graefe reported the first one in 1864. Bertoldi collected 43 by 1941, and the author adds four of his own. Photomicrographs and colored pictures accompany the extensive case reports; a painstaking discussion of the characteristics of these rare tumors follows. The patients are usually more than 40 years of age and of either sex. The majority of these tumors involve the upper lid. Chalazea or simple adenomas may be the forerunners of the Meibomian carcinoma. Metastasis in lymphatic nodes has rarely been found, and generalized metastasis occurred in only eight of the published cases. Differential diagnosis in biopsies is difficult because of the lack of definite signs of malignancy in tumors of rapid growth and invasive type. In the carcinomas of the Meibomian glands, the characteristic seems to be a rapid "sebaceous maturity" which also is encountered in the metastatic tumors.

Surgery with subsequent irradiation is recommended. K. W. Ascher.

White, J. P., and Lowenstein, A. Unpigmented primary tumor of the optic disc. *Brit. Jour. Ophth.*, 1946, v. 30, May, pp. 253-260. (See Section 11; optic nerve and toxic amblyopias.)

16

INJURIES

Alagna, G. Hydrocyanic acid intoxication and the eye. *Ann. di Ottal.*, 1946, v. 73, April, pp. 217-233.

An eight-year-old boy died of hydrocyanic acid poisoning about twelve hours after eating some thirty apricot seeds. Ophthalmoscopic examination a few minutes before death showed diffuse edema of the retina of each eye, with a cherry-red spot at the macula; the optic disc was hazy and its margin was blurred. The ophthalmoscopic picture was on the whole very much like that of recent closure of the central retinal artery. Histologic examination showed atrophic and degenerative changes in the retina and optic nerve. The ganglion cells and nerve fibers were particularly affected. There was no involvement of the anterior segment of the eyes or of the adnexa.

The lesions in the retina and optic nerve are attributed to the direct action of the acid upon the nerve cells and their fibers. The acid acts by paralyzing the mechanisms of oxidation, with resulting asphyxia of the vulnerable third neuron.

Belmonte Gonzalez, N. and Vidal Frias, J. Localization of intraocular foreign bodies by means of the radiographic visualization of the globe with contrast substances. *Arch. de la Soc.*

Oft. Hisp.-Amer., 1945, v. 5, July, pp. 558-565.

The author demonstrates the importance of the use of contrast substances to facilitate the localization of intraocular foreign bodies. This is done by using Per-Abrodil, which is injected into Tenon's capsule. It is easily done, is not expensive and not dangerous.

J. W. McKinney.

Cruthirds, A. E. Importance of sulfhydryl in the treatment of corneal and X-ray burns. *Am. J. Surg.*, 1946, v. 72, Oct., pp. 500-509.

In X-ray burns one is not to be concerned only with the burn but with an injury which leaves the underlying tissue devitalized. The skin contains 60-percent of the sulfur in the body. A serious or extensive burn disturbs the sulfur metabolism.

In the eye, as elsewhere in the body, all the minerals are present but potassium and sulfur predominate. Glutathione, containing -SH groups (sulfhydryl), is present in large quantity in the normal lens and is said to be essential for tissue oxidation. The cataractous lens has been found devoid of glutathione.

Over 500 cases of burns involving the eyes and adjacent areas were treated with a high concentration of sulfhydryl, a colloidal sulfur compound that stimulates epithelium. Its proprietary name is hydrosulphosol.

In an eye with extensive multiple pneumococcal corneal ulcers with hypopyon so severe that enucleation was considered, recovery promptly followed subconjunctival and parenteral application of penicillin and hydrosulphosol eye drops and packs. The author has not observed such excellent results with penicillin alone.

The drug is neither toxic nor incom-

patible with other drugs. When sprayed on the skin it quickly forms a dry flexible membrane which requires no other covering. The results in infected, indolent X-ray burns have been most gratifying. Francis M. Crage.

Dejean, C., and Sedan, J. A clinical and experimental study of corneal lesions caused by indelible pencil and their treatment. *Revue Bulgare d'Opht.*, 1943, v. 2, pp. 75-83. See Section 6, cornea and sclera.)

Esteban, Mario. The estimation of ocular disability in industrial injuries. *Arch. de la Soc. oft. Hisp.-Amer.*, 1945, v. 5, Nov., pp. 965-980.

The author discusses various methods for the estimation of visual disability after industrial accidents. He makes a plea for a standardized method, such as is used in the United States, and for a routine preemployment ocular examination of workers. The tables for the evaluation of ocular war injuries as adopted in May 1938 is given in entirety. Ray K. Daily.

Farnarier, G. Extraction of foreign bodies without provoking cataract. *Ann. d'Ocul.*, 1946, v. 179, March, pp. 163-165.

Magnet extraction of foreign bodies from the anterior part of the lens with immediate contraction of the pupil as advised by Elschnig was successfully used by the author. The miosis produces an adhesion between the iris and the anterior lens capsule which theoretically prevents aqueous from coming in contact with lens substance. The pupil at the time of operation is best dilated with a subconjunctival injection which does not interfere with eserine myosis. Obviously, the foreign substance must be small and magnetic,

located near the anterior lens capsule and be neither central nor too peripheral. Its extraction must be performed almost immediately after injury.

Chas. A. Bahn.

Guy, L. P. Use of Berman locator in removal of magnetic intraocular foreign bodies. *Arch. of Ophth.*, 1946, v. 36, Nov., pp. 540-550.

Experience with the Berman Locator has demonstrated that the best foreign body work cannot be done without it. It is a portable electromagnetic device that is self-sufficient in many cases for all preoperative and operative localization of magnetic foreign bodies.

In the operating room, the Locator provides localization of pinpoint accuracy with which to check and, if necessary, to correct the roentgenologic localization previously obtained and provides information as to how much magnetic force is necessary. Its detecting element is sufficiently small for use in intraocular foreign body work and can be sterilized.

The combined use of the Locator with roentgenograms meets most of the ideal requirements for localization of foreign bodies. The roentgenogram discloses the presence of the foreign body, its dimensions and its position. The Locator tells whether it is magnetic and approximately to what degree.

As a probe approaches the site of the foreign body, the meter needle rises on the scale, and simultaneously the sound from the speaker rises in pitch. The position on the surface where the peak indication is obtained marks the precise spot for incision. The principles, care, and manner of use of the instrument are described.

R. W. Danielson.

Hughes, W. F., Jr. The treatment of Lewisite burns of the eye with BAL. *J. Clin. Invest.*, 1946, v. 25, July, pp. 541-548.

When relatively small quantities of Lewisite liquid or vapor come in contact with an eye a devastating ocular lesion results. There is rapid tissue necrosis, marked conjunctival and corneal edema, and intense exudation. On contact with the moist surface of the eye, Lewisite immediately hydrolyzes with the production of an arsine-oxide and hydrochloric acid. The superficial corneal opacity produced by this acidity prevents BAL from having any beneficial effect on the eye.

Within ten minutes after exposure to Lewisite there is histological evidence of damage in all tissues of the anterior ocular segment, indicating deep penetration and rapid necrotizing action.

Over 600 rabbit eyes were exposed to Lewisite. No residual toxic material or arsenic remained on the corneal surface within two to four minutes after the instillation of the liquid Lewisite into the eye followed by the closure of the lids. A single instillation of BAL solution or ointment within two to five minutes after exposure to Lewisite, effectively prevented the development of serious ocular lesions. The excellent therapeutic effect of BAL is due, in part at least, to its rapid penetration and neutralization of toxic arsenical material in the tissues before irreversible histologic changes have developed. If treatment is delayed five minutes, the Lewisite reaction lasts a few days. If delayed 10 minutes corneal opacities are still present at the end of a week. When used within 30 minutes BAL lessens the severity of the process, but permanent damage to the eye remains.

F. M. Crage.

Hughes, W. F., Jr. Alkali burns of the eye. *Arch. of Ophth.*, 1946, v. 36, Aug., pp. 189-214.

This is a detailed clinical and pathologic study of the course of alkali burns, based largely on sodium hydroxide burns of the rabbit eye. During the acute stage there is ischemic necrosis and edema of the conjunctiva and limbal region of the sclera, sloughing of the corneal epithelium, histologic evidence of rapid and deep penetration of the alkali with necrosis of cells in the corneal stroma and endothelium, loss of corneal mucoid, edema of the corneal stroma and ciliary processes, and infiltration of polymorphonuclear cells into the cornea and iris.

During the reparative stage there is subsidence of conjunctival and corneal edema, regeneration of the conjunctival and corneal epithelium, vascularization of the cornea, clearing of the corneal opacification, proliferation of elongated mononuclear cells at the periphery of the burned area in the corneal stroma, regeneration of the corneal endothelium, and disappearance of the iritis.

During the stage of late complications there may be localized corneal infiltrations, progressive or recurrent corneal ulceration, overgrowth of the cornea with a vascularized membrane, permanent corneal opacification, staphyloma of the cornea, persistent or exudative iritis, glaucoma, cataract, and symblepharon.

Unlike the nonprogressive course of acid burns, alkali penetrates rapidly and deeply into the anterior ocular segment, and mucoid disappears from the involved corneal stroma. (41 photographs.)

John C. Long.

radiant energy. *Trans. Amer. Acad. Ophth.*, 1946, July-Aug., pp. 230-240.

All radiations longer than 30,000 A.U. are absorbed in the cornea. A progressive increase in transmission occurs to 11,000 A.U., where 90 percent of luminous energy is transmitted through the cornea. Infrared rays of 10,000 A.U. are transmitted by the lens and absorbed by the iris. The retina receives practically none. Absorbed infrared rays raise the tissue temperature and if strong enough cause immediate thermal damage. Prolonged and severe exposure causes lens opacities that begin in the axial and posterior part. Splitting of the anterior capsule with free margins floating in the anterior chamber is the first stage of glass blowers' cataract caused by prolonged exposure to radiation of wave lengths from 10,000 to 18,000 A.U. Visible rays from 3,900 to 7,800 A.U. are transmitted through the ocular media to the rods and cones where the surplus is transformed into heat and may cause a thermal burn. The lens absorbs ultraviolet rays from 3,200 to 3,800 A.U., the cornea absorbs those below 3,200 A.U. Ultraviolet rays penetrate the tissues and may produce abiotic effects. After a latent period of six to eight hours after exposure, pain, lacrimation and corneal dullness frequently occur. Several months may elapse before gamma radiations of X ray and radium have their full effect. A disc-shaped opacity at the posterior pole of the lens surrounded by a ring of minute discrete opacities may be produced. Opacities in the capsule or beneath it may be caused by lightning and electric currents. For protection against excessive infrared rays, lenses that contain ferric oxide are of service; for excessive ultraviolet light exposure, cobalt lenses are preferable.

Kutscher, C. F. Ocular effects of

Leaded equipment is necessary to protect the tissues from gamma rays.

Chas. A. Bahn.

Law, Frank. W. *Minor injuries of the eyes.* Jour. of Social Ophth., 1946, v. 3, July, pp. 3-14.

The author describes the treatment of "black eye," commotio retinae, abrasion and laceration of the conjunctiva, foreign bodies, burns, and radiation injuries. Fluorescein should always be instilled to determine the extent of surface injury. The shape of the pupil and depth of the anterior chamber are the most reliable external signs of intraocular damage. Blood in the eye or a black pupillary reflex indicates a major injury. Whenever intraocular foreign bodies are suspected an X-ray examination should be made.

I. E. Gaynon.

Mathis, G. *Ocular lesions due to vapors of fluorine and its derivatives.* Rassegna Ital. d'Ottal., 1941, v. 10, May-June, p. 327.

The observations of 57 cases of palpebral and conjunctival irritation, caused by direct contact or exposure to fumes of fluorine, among 252 workers, are reported. The pathologic changes observed were simple conjunctival irritation, acute conjunctivitis, chronic catarrhal conjunctivitis, sometimes limited to the bulbar portion exposed between the lids, eczema of the lids, and three instances of bilateral pterygium.

E. M. Blake.

Rebello Machado, Nicolino. *Contribution to tropical Brazilian ophthalmology.* Rev. Brasileira Oft., 1946, v. 5, Sept., pp. 5-15.

The first part of the article gives two cases of direct wasp sting in the

sclera and the cornea respectively. The former was in a 12-year-old black girl. The vision of the affected eye was completely abolished. There was a severe iridocyclitis with hypopyon and diminished tension. The sting had occurred 7 mm. outward from the limbus. Later probing through the 2-mm. opening at this point suggested the presence of intrabulbar suppuration. At evisceration, the vitreous was found completely disorganized and purulent.

The second case occurred in a 34-year-old male Brazilian Negro. The cornea was stung but not completely penetrated at the five o'clock position, 2 mm. from the limbus. Vision, at first reduced to light perception, returned to normal, and only a slight nebula remained at the site of the injury. Both cases occurred along the coast, and probably both were due to the wasp *Synoecca Surinana*.

The second part of the paper deals with injury by toxic vegetable substances that occur especially in woodsmen, usually when engaged in cutting down trees. The most frequent offender appears to be a member of the family Euphorbiaceae, probably ophthalmoblapton pedunculare Muell, known by the local inhabitants as Cega-Miguel or Cega-Maria (Blind Michael or Blind Mary). This and similar plants possess a caustic sap or latex. Two cases are reported in woodsmen aged 23 and 34 years respectively, who had been engaged in cutting down trees in the forest, and received splashes of the sap in one eye. In each the vision, at first considerably disturbed by the effect on the cornea, returned more or less definitely to normal. Other offenders are the tree euphorbia called Uassacú, the oil of the castor plant, Podophyllin, and Jequirity. The products of these

plants are not infrequently used for simulation. (References.)

Stallard, H. B. **Retinal detachment due to war trauma.** *Brit. Jour. Ophth.*, 1946, v. 30, July, pp. 419-429. (See Section 10, Retina and vitreous.)

Webster, J. E., Schneider, R. C., and Lofstrom, J. E. **Observations upon the management of orbitocranial wounds.** *J. Neurosurg.*, 1946, v. 3, July, pp. 329-336.

A survey of 40 cases of orbitocranial wound was made. In 20 patients (Group 1) the globe was injured, requiring enucleation, and in 20 (Group 2) the bony orbit was involved with varying degrees of injury to the functions of the globe.

Patients in Group 1 required the enucleation of one or both globes, a procedure which may be done to advantage before the cranial wound is attacked. The use of implants after enucleation depended upon the degree of disorganization of the orbital contents.

Twelve patients in Group 1 presented varying types and degrees of intraocular injury with complete or incomplete loss of vision. In eight patients the vision was normal. The predominant disturbance that resulted in loss of vision was of vascular origin. The commonest findings were vitreous and retinal hemorrhages with tearing and detachment of the retina. Proptosis of the globe was frequently present with these lesions. In one patient the detachment of the pulley of the superior oblique muscle was disrupted. In another, total blindness resulted from a fragment that entered the roof of the orbit posteriorly. Evaluation of the type and degree of damage

to the globe and the optic nerve by either the fragment or the concussive effects of injury was difficult to make in the early period of management.

Massive wounds of the orbitocranial wall were satisfactorily managed by means of a temporary graft of fascia lata applied to the dural defect. An osteoplastic frontal craniotomy flap exposure was effective in dealing with wounds in this area in some cases. Complicating brain abscesses were treated by an "open" method using a graft of fascia lata to close the dura temporarily and isolate the brain from the sinuses. A split thickness graft was applied to the wound after removing the temporary fascial graft.

Theodore M. Shapira.

Zolotnizki, I. I. **Perforating ocular injuries.** *Oftal. Jour. (Odessa)*, 1946, pt. 2, pp. 25-29.

Fifteen cases are reported to show the gravity of ocular perforations associated with injuries of the skull, and the necessity for careful diagnosis before doing an enucleation, in order to avoid fatal meningitis. The author urges that every ocular perforation associated with injury to the superior orbital wall be regarded as an intracranial injury, with obligatory X-ray and neurological examination.

Bietti, Giambattista. Rare and atypical forms of cranial and craniofacial dysostosis with ocular complications. *Boll. d'Ocul.*, 1945, v. 24, April-June, pp. 83-136.

The writer reports four cases of dysostosis of the bones of the skull and face. A girl 13 years of age showed marked acrocephaly, the disappearance of cranial sutures, basilar lordosis and flattening of orbits. The digits of her hands and feet were of the Marfan type and this was present in different members of her mother's family. A symptom that she had in common with the mother was the tortuosity of the

retinal vessels and with the father the myelinated fibres at the optic disc. The other three observations were made in a family among the members of which the mother, a son, and a daughter had dysostotic changes of the skull and face. The mother showed more marked lesions in the right half of the head and had exostosis of the skull. The son showed a craniofacial dysostosis of the Crouzon type and the daughter showed an atypical dysostosis with syndactyly. Three other children were free from symptoms. Among the ocular lesions common to all, the writer mentions exophthalmos, divergent strabismus, and optic atrophy. The writer classifies the form of craniofacial dysostosis. (Bibliography, 19 figures.)

Melchior Lombardo.

Bookstaver, P. I. Horner's syndrome. *U. S. Naval Med. Bull.*, 1946, v. 46, April, p. 567.

The author describes a classical Horner's syndrome, noted within 24 hours after the patient was wounded by a Japanese bullet that penetrated the right side of the neck. There was also a bruit in the neck which suggested a traumatic arteriovenous aneurysm.

Benjamin Milder.

Cavara, Vittoriano. The ocular manifestations of herpetic infection. *Boll. d'Ocul.*, 1946, v. 25, Jan.-June, pp. 3-296.

The subject is comprehensively discussed in 13 chapters: 1, the generalities of herpetic infection, 2, herpetic manifestations in the eye in general, 3, herpetic eruption of eyelids, 4, herpetic manifestations of the conjunctiva, 5, herpes of the cornea, 6, herpetic lesions of sclera and episclera, 7, of the uvea, 8, of the optic nerve, 9, of the ocular nervous apparatus, 10, ocular

lesions from herpetic virus and other associated germs, 11, diagnosis of ocular herpetic manifestations, 12, prognosis of ocular herpetic manifestations, and 13, therapy and prophylaxis of the ocular herpetic manifestations. Each chapter has a bibliography. (119 figures.) Melchior Lombardo.

Cockayne, E. Dwarfism with retinal atrophy and deafness. *Arch. Dis. Childhood*, 1946, v. 21, March, pp. 52-54.

The author describes a sister and a brother first in 1936 and again in 1946. The condition, which is probably recessive, appears to be a definite entity not previously described. It is characterized by dwarfism with prognathism, thickening of the skull bones, and other skeletal changes, a peculiar form of retinal pigmentation, optic atrophy, and cataract, deafness, and mental deficiency. Theodore M. Shapira.

Duggan, W. F. Vascular basis of allergy of the eye and its adnexa. *Arch. of Ophth.*, 1946, v. 36, Nov., pp. 551-611.

This excellent paper is essentially a monograph of the literature of the allergic manifestations in all the tissues of the eye.

To most physicians allergy means "hypersensitivity" to protein, whether of plant, animal or bacterial origin. The author includes all those aseptic or abacterial lesions in which the basic pathologic process can be reduced to the common denominator of either increased capillary permeability or excessive contraction (spasm) of smooth muscle or both. The only difference between the normal and the allergic person is one of degree. Every one probably has minor or transitory allergic manifestations during life. Al-

lergic patients have more severe and more frequent attacks of allergy.

The relation of histamine to allergy is discussed in detail. Allergy of the ocular tissues can be interpreted as a manifestation of localized vascular dysfunction. This vascular dysfunction causes areas of localized tissue anoxia. Anoxemia is not usually, or necessarily, present.

Vasodilator therapy, which acts by relieving the tissue anoxia, seems to be of value in the treatment of the allergic lesions of the eye. This treatment is based on the pathologic physiology of the lesions. R. W. Danielson.

Duke-Elder, Sir Stewart. Nutritional aspects of ophthalmology. *Irish J. Med. Sc.*, 1946, 6th series, June, pp. 177-189.

The author describes the ophthalmologically important vitamins A, B, C, and D and the affects of vitamin deficiencies on the various structures of the eye. Theodore M. Shapira.

Gabardi, E. F. and Zanello, D. Oculomedullar syndrome caused by a metastasis of a pancreatic carcinoma. *Riv. Oto-Neuro-Oft.*, 1941, v. 18, no. 3, pp. 199-244.

A 9-year-old boy developed bilateral choked discs, proptosis, severe chemosis, blindness and immobility of both eyes, and later nodules beneath the skin of his face and neck. It was not until six months later that the primary lesion, a pancreatic carcinoma, produced clinically recognizable symptoms. A flaccid paraplegia occurred two days before death. Extensive carcinomatous infiltration of the spinal leptomeninges was found at necropsy. (33 illustrations, more than 150 references.) K. W. Ascher.

Gorduren, S. **Conjunctival findings in cases of cold haemagglutination.** *Brit. Jour. Ophth.*, 1946, v. 30, Oct., pp. 613-616.

The conjunctiva of two patients suffering from cold haemagglutination were chilled by the application of cold isotonic salt solution. The temperature of the salt solution varied from 37 to 0 degrees centigrade. The vessels underwent marked constriction with agglutination of the red cells. The blood columns became segmented. At 27 degrees this occurred in 45 seconds and the vascular pattern returned to normal in 45 to 60 seconds. At the freezing point the phenomenon developed in 3 to 5 seconds and disappeared in 150-170 seconds. Morris Kaplan.

Lopez, P. M. **Ocular symptoms and complications of epidemic cerebrospinal meningitis.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Oct., pp. 871-883.

The material for this study comprises 102 patients, of whom 57 had ocular complications. It is pointed out that ocular complications are recorded principally on patients who were examined by ophthalmologists. Pediatricians or internists are apt to overlook ocular symptoms. In as much as the conjunctival sac may be the initial site of infection with the meningococcus, Lopez urges that during epidemics cultures for the meningococcus should be made in all cases of conjunctivitis. People exposed to the disease should be watched.

The severity of the ocular symptoms appears to be proportional to the severity of the disease, and Lopez divides the cases into severe, moderately severe, and mild. The tabulated data show that among the severe cases, which constituted 25 percent of the

total number, there were three of amaurosis with normal fundus and pupillary reactions, caused by the toxic action on the higher visual centers; three of spasmodic strabismus; two with conjugate deviation; four with rigidity; eight with Goppert's sign, which is a pupillary dilatation in response to slight stimulation of the skin; two with papillitis due to a descending neuritis; one of papillary edema caused by an inflammation of the choroidal plexus; one of keratitis, not of the neuroparalytic type; two cases of endophthalmitis.

In the moderately severe cases, which represent 35 percent, the predominating complications were transient optic neuritis, transient strabismus due to involvement of the sixth nerve, muscular rigidity, Goppert's symptom, and irido-cyclitis. In the mild cases, constituting 42 percent, the ocular complications were insignificant.

The author's experience confirms the prevalent opinion that the most effective therapy is intensive administration of sulfa drugs and lumbar punctures. In cases of endophthalmitis and panophthalmitis hemotherapy with the blood of parents was used in addition to sulfatherapy and with benefit; the parents were first saturated with sulfa drugs and their blood, mixed with a foreign protein, was injected intramuscularly. Ray K. Daily.

Pirisi, B., and Mesina, R. **Lawrence-Moon-Bardet-Biedl Syndrome.** *Riv. Oto-Neuro-Oft.*, 1941, v. 18, Sept.-Oct., pp. 361-420.

An extensive review of 152 cases published up to 1941 is presented, and two (brother and sister) observations of his own are reported. These two patients had retinitis pigmentosa sine pigmento, hemeralopia, nystagmus,

adiposity, genital dystrophy, mental debility, mongoloid faces, and dental anomalies, but no polydactyly, except for one foot which had six toes. (12 figures, bibliography.)

K. W. Ascher.

Rossi, V. Reticulo-endotheliosis in ophthalmology. *Arch. di Ottal.*, 1946, v. 50, Jan. and Feb., pp. 1-19.

Rossi reviews the literature on the reticulo-endothelial system in general medicine and ophthalmology. One patient is described who had a generalized glandular enlargement and nodules in both upper fornices. There was a monocytosis of 25 to 27 percent. In the diagnosis the syndrome of Heerfordt and Mickulicz disease, both diseases of the reticulo-endothelial system were considered. The diseases of Nieman-Pick, Gaucher, and Christian-Schüller are in the same group.

Another patient was thought to have involvement of the choroid by mycoses fungoides. There were edema of the papillae, moderate hemorrhages and extreme dilatation of the veins, a papulous erythema of the lids, intense hyperemia of the conjunctiva, and enlargement of the preauricular gland. Later this patient returned. He was amaurotic, and in the yellow fundus, all landmarks were completely erased. The similarity to von Hippel-Lindau disease without cystic degeneration and detachment but with proliferation of the reticulo-endothelial elements of the retina and the neuroglia is noted.

Francis P. Guida.

Wagener, H. P. Temporal arteritis and loss of vision. *Am. J. Med. Sc.*, 1946, v. 212, Aug., pp. 225-228.

Inflammation of the temporal artery occurs in those of advanced age and is probably a local manifestation of a

systemic arterial disease. In about one third of the patients there is loss of vision. In some the visual loss arises from central artery closure, in others venous phlebitis in the retina with hemorrhages and exudates.

Johnson, Harley, and Horton suggested the possibility of a direct extension of the lesion from the temporal arteries into the arteries of the optic nerve. They found that vasodilator drugs were harmful. The loss of vision may be out of proportion to the visible changes in the disc and retina. Sudden complete blindness with a normal fundus may be due to ischemic or anoxic retrobulbar neuritis. The ophthalmoscopic lesions fall into three groups: closures (thrombosis) of the central artery of the retina or of branch arterioles, ischemic optic neuritis, and indeterminate. The neuritic type is the most common.

More general recognition of this syndrome will help to explain sudden complete or partial loss of vision in elderly individuals. Retinal arterial closure with atypical visible lesions should make one suspect temporal arteritis. Loss of vision during the stage of active inflammation when the temporal arteries are cordlike and tender, pain on fatigue on chewing makes the diagnosis easy. If visual loss occurs late a history of inflammation of the temporal arteries helps in diagnosis.

Francis M. Crage.

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Allen, T. D. A small plant industrial eye program. *Trans. Amer. Acad. Ophth.*, 1946, May-June, pp. 205-210.

Ophthalmic examinations and placement programs for employees based

on these examinations have not been suitable financially for smaller plants of 200 to 500 employees. The Illinois Society for the Prevention of Blindness made available the services of a safety engineer, illuminating engineer, and a visual survey technician at the cost of one dollar per employee examined. These examinations were made in several small manufacturing plants and the results were very satisfactory. The accident rate was materially reduced after the examinations were made and corrective measures were adopted. Chas. A. Bahn.

Anastossoff, A. The scientific and social work of Constantin Pascheff. *Revue Bulgare d'Ophth.*, 1943, v. 2, pp. 1-34.

This is a detailed review of Professor Pascheff's numerous papers and an evaluation of their importance for general pathology, as well as for every branch of ophthalmology. His contributions towards an improvement of the Public Health Service and the service for the visually handicapped and blind in Bulgaria are emphasized. (References.) Alice R. Deutsch.

Cisney, Harland N. Vision testing in an automotive accessories industry. *Trans. Amer. Acad. Ophth.*, 1946, March-April, pp. 170-174.

Four thousand individuals were examined visually at 26 feet and 13 inches. Visual acuity with both eyes together and with each eye separately as well as phorias, vertical and lateral, depth perception, and color discrimination were measured at 26 feet and visual acuity and phorias at 13 inches. It was found that 75 percent of those who passed the approved visual standards were rated as good operators whereas only 33 percent of those who

did not meet the standards were rated as good operators. Wall charts for testing distant vision are less efficient than modern mechanical methods if properly used. Chas. A. Bahn.

Cooper E. L. A method for classifying employees for selective placement. *Trans. Amer. Acad. Ophth. and Otolaryng.*, 1946, Jan.-Feb., pp. 135-139.

Only near and distant visual acuity is needed for the routine examination of employees in industry. The combined visual efficiency of the two eyes is then computed in accordance with the formula of the A.M.A. committee on compensation for eye injuries. All examinees are divided into three groups: physically qualified (P.Q.), not physically qualified (N.P.Q.) and physically qualified with exceptions (P.Q.X.). Those who are rated N.P.Q. are not visually eligible for any position. Those rated P.Q. are eligible for positions ranging from the lowest to the highest visual requirements. Special examinations such as those for muscle balance, color perception, and depth perception are made for examinees qualifying for positions requiring these tests. The group P.Q.X. includes those who have handicaps which exclude them from some occupations but not all.

The system has the advantage that it can be readily adapted to the requirements of any employer without special medical personnel or special testing equipment. It eliminates unnecessary routine testing but provides supplementary tests in specific fields of effort. Charles A. Bahn.

Dickson, R. M. A statistical analysis of persons certified blind in Scotland. *Brit. Jour. Ophth.*, 1946, v. 30, July, pp. 381-405.

In this complete, detailed study of the 7,297 registered blind of Scotland many interesting facts are found. Causes of blindness in order were: cataract, 17.1 percent; myopia, 14.9 percent; chronic septicemia, 10.8 percent; syphilis, 10.0 percent; glaucoma, 8.1 percent; injury, 5.9 percent. Since the first two appear latest in life, they accounted for fewer years of blindness while such causes as congenital anomalies, ophthalmia neonatorum, and congenital lues accounted for 44.5 percent of the total years of blindness. The highest incidence is among miners, metal workers, spinners, and weavers. In Scotland, a person is legally blind if he has less than 3/60 vision or the visual fields contracted to 10 degrees although the vision may be 6/60 or better. (22 tables.)

Morris Kaplan.

Ehlers, Holger. **The Causes of Blindness in Denmark.** *Jour. of Social Opth.*, 1946, v. 3, July, pp. 23-28.

Smallpox, trachoma, ophthalmia neonatorum, scrofula, and xerophthalmia (during World War I) have been eliminated as causes of blindness. The causes now are congenital anomalies such as malformations, microphthalmia, congenital cataract, retinitis pigmentosa, amotio retina, and optic atrophy. There has been a great increase in the number of patients with weak eyesight in the past ten years, whereas the number of patients attending a school for the blind show a marked decline. I. E. Gaynon.

Gradle, H. S. **Graduate training in ophthalmology—Jackson Memorial Lecture.** *Trans. Amer. Acad. Opth. and Otolaryng.*, 1945-46, Sept.-Oct. pp. 10-14.

The evolution of graduate training and the accomplishments of the American Board of Ophthalmology are reviewed. The need of standardized ophthalmic training between the completion of the intern year and certification by the Board is emphasized. The plan recommended would include training in basic science for three to six months at a university and medical school. In this course laboratory demonstrations and directed conferences and quizzes would be of first importance. The basic training would be followed by a period of clinical training of not less than two years. This would be given preferably in special university hospitals or general hospitals, if a sufficient staff could be secured. Conferences and seminars would take up major and important subjects. If possible, this training should lead to a degree and automatic certification by the American Board of Ophthalmology. Chas. A. Bahn.

Jablonski, Walter. **Ophthalmological impressions in the Orient.** *Ophthalmologica*, 1946, v. 112, July, pp. 39-46.

Jablonski visited Palestine, Egypt, and Cyprus. He noted a preponderance of external eye diseases and their resulting deformities. Koch-Weeks conjunctivitis breaks out with surprising regularity and vehemence about three months after the last rains and is often complicated by corneal ulcer. It is usually followed by an epidemic gonorrhoeal ophthalmia which in the Orient is transmitted from eye to eye and causes most of the blindness. Toward the end of the summer an epidemic conjunctivitis is observed that resembles swimming pool conjunctivitis. It occurs more frequently in the coastal plains than in the mountains.

Throughout the year one sees vernal conjunctivitis, diplobacillus conjunctivitis, and the ubiquitous trachoma. The latter usually is treated surgically. Fly larvae in the conjunctival sac are found occasionally. Corneal fistulas, descemetocoele, (following corneal ulceration) and purulent dacryocystitis are common. Metasyphilitic eye symptoms are rare, perhaps because the population is infected with malaria. Tobacco-alcohol amblyopia is almost never seen. Early cataract formation seems to be common and certainly glaucoma, often starting in youthful age, is relatively frequent. All hereditary degenerations and malignant myopia are common, probably because of marriage among blood relatives. (References.)

F. Nelson.

Massoud, F. Egypt's contribution during the war to protection against disease through care of eyes of babies. *Brit. Jour. Ophth.*, 1946, v. 30, Oct., pp. 617-622.

A program of prevention of trachoma and ophthalmia was carried out, so successfully that in many areas 70 to 90 percent of the eyes of children are normal and in some public schools all pupils have healthy eyes. (3 tables.)

Morris Kaplan.

Minton, Joseph. Ophthalmic problems and visual standards in industry. *Brit. Jour. Ophth.*, 1946, v. 30, May, pp. 298-303.

A plea is presented for more widespread and more intelligent use of routine ophthalmic examinations in industry.

Morris Kaplan.

Neubert, F. R. Ophthalmic experiences in the Royal Air Force. *Brit. Jour. Ophth.*, 1946, v. 30, Oct., pp. 601-606.

A statistical analysis of the results of the ophthalmic examination of candidates for air crew duties is reported. The tests done were visual acuity, manifest hyperopia, cover test, Maddox rod, Bishop Harman test, convergence, accommodation, visual fields (confrontation), color vision and fundus examination.

Morris Kaplan.

Poleff, L. Necessity of an international study center of trachoma. *Brit. Jour. Ophth.*, 1946, v. 30, May, pp. 287-290.

The author presents a plea for the establishment in Morocco of an international center for the study of trachoma, the greatest medical scourge of the world today.

Morris Kaplan.

Pollock, W. B. I. Arabian ophthalmology. *Brit. Jour. Ophth.*, 1946, v. 30, Aug., pp. 445-457.

An interesting, detailed history of ophthalmology in Arabia and Persia from the 9th through the 13th century is presented. Of most interest was the operation for cataract in which the surgeon inserted a small hollow tube into the lens and sucked up as much of the contents as possible.

Morris Kaplan.

Redway, L. D. Plant experience with metallic stencils. *Trans. Amer. Acad. Ophth.*, 1946, Jan.-Feb., pp. 139-141.

Metallic stencils used for addressing mail must be checked before and after use, which requires a high degree of binocular function, accurate depth perception, and manual cooperation. The stencils act as metal mirrors which cause uncomfortable flashing reflections. Overhead fluorescent lighting of 65 foot candles at working height and the wiping of the stencils with a quick

drying ink materially reduced these ocular symptoms. The author believes that the usual visual screening methods should not be interpreted too rigidly.

Chas. A. Bahn.

Reed, H. Incidence of trachoma in the Southern Highlands Province of Tanganyika. *Brit. Jour. Ophth.*, 1946, v. 30, Oct., pp. 573-580.

This study attempts to explain the definite geographic variation of trachoma among the Africans. The incidence among all natives in this province was about 50 percent and yet it varied from 13 to 87 percent in the various districts. The disease was generally mild and uninfluenced by climate or other geographic factors. Occupation which determined the state of personal cleanliness seemed important. The incidence was greatest where raising of cattle brought flies.

Morris Kaplan.

Reeh, M. J., Stimmel, E. W., and Heagan, F. V. A motor-driven ophthalmotrope. *Amer. Jour. Ophth.*, 1947, v. 30, Jan., pp. 58-59. (3 figures.)

Rodin, Frank H. *Eserine: its history in the practice of ophthalmology*. *Amer. Jour. Ophth.*, 1947, v. 30, Jan., pp. 19-28. (7 figures, references.)

Sbikowski, Enrique de. Prevention of ocular accidents. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Jan., pp. 82-84.

The author asks that failure to carry out protective measures should be recorded in the case records of traumatic accidents. The ease with which serious accidents can be avoided should be explained to the injured. The importance of preëxisting diseases, especially of dacryocystitis, in the aggravation of otherwise minor injuries should be

pointed out and dacryocystitis should be included in the list of reportable diseases. He advocates preliminary visual examination as a means of vocational adjustment, the correction of defects and refractive errors, and the elimination of agents injurious to the human eye from the home, the school, and industry.

Ray K. Daily.

Smith, F. L. Visual skills analyzed brings results; a plant experience. *Trans. Amer. Acad. Ophth.*, 1946, March-April, pp. 174-175.

A direct correlation was found between visual skills in successful employees and their lack in employees who failed. Since the introduction of a visual examination and follow-up program, complaints of eye strain in positions demanding visual skills have markedly diminished.

Chas. A. Bahn.

Sorsley, A. Nineteenth century provincial eye hospitals. *Brit. Jour. Ophth.*, 1946, v. 30, Sept., pp. 501-546.

This comprehensive historical account of all the eye hospitals in the British Isles in the nineteenth century reveals the fact that 52 such hospitals were founded and used and only 18 of them remain today.

Morris Kaplan.

Souza, J. L. de. Luzia, protector of the eyes. *Arquivos Brasileiros de Oft.*, 1946, v. 9, April, pp. 49-64.

According to the ecclesiastical record, Santa Luzia (or Lucia) was a Christian virgin who underwent martyrdom in Siracusa in the year 304, in the Diocletian persecution. She appears to be referred to in an epitaph found in Saint John's catacombs (Siracusa), and her name is attached to a Mass in the Gregorian Sacrament

(A.D. 590-604). Her remains were removed from the Siracusa catacombs to a cathedral dedicated to her at Corfino in the dukedom of Spoleto, and later were taken to Metz. Although usually depicted as carrying in her hands a tray on which are seen two eyes, there is nothing in the history of her life and death to suggest anything connected with eyes. It is possible that confusion has arisen from the fact that her saint day is the same as that of Saint Odilia, who is said to have been born blind and to have recovered her sight upon baptism by the Bishop of Ratisbon. (References.)

W. H. Crisp.

Stump, F. N. How ophthalmic eye care can prevent many industrial accidents. *Trans. Amer. Acad. Ophth.*, 1946, July-Aug., pp. 219-225.

The author believes that 98 percent of industrial accidents are preventable. Based on an Ortho-Rater examination in numerous plants a statistical resume is given and a pattern of requirements is made for different vocations. Three separate groups are compared. Sixty more employees in the accident-free group had standard visual acuity than in the seriously injured group. In the accident-free group 68 percent more had standard depth perception than in the seriously injured group. New employees farthest below visual standards had 75 percent more accidents than those who were acceptable.

Chas. A. Bahn.

Swanson, C., and Stewart, R. A. Causes of blindness in U. S. Naval and Marine Corps. *U. S. Naval Med. Bull.*, 1946, v. 46, April, p. 520.

The causes in 119 cases of bilateral blindness, and 640 cases of unilateral blindness, reported in the U. S. Navy

and the Marine Corps during World War II, until January 1, 1945 are classified. Of bilateral blindness, 60 percent, and of unilateral, 50 percent, was traumatic and due to enemy action. Sixteen percent of the bilateral blindness resulted from methyl alcohol poisoning.

Taylor, W. O. G. Occupational therapy in eye wards. *Brit. Jour. Ophth.*, 1946, v. 30, Aug., pp. 456-461.

The author indicates the usefulness of occupational therapy in eye wards and lists nine crafts that are suitable for eye patients who need occupational therapy. Special warning is given to omit basketry because of its general association with blindness. (6 illustrations.)

Morris Kaplan.

Tiffin, J., and Wirt, S. W. Determining visual standards for industrial jobs by statistical methods. *Trans. Amer. Acad. Ophth.*, 1945, Nov.-Dec., pp. 72-93.

Visual requirements for employment may be based on arbitrary opinions of standards required and on statistical facts which determine the necessary minimum requirements for a specific position. By the statistical method the selection of better workmen is facilitated, employees with different visual skills can be allocated to appropriate jobs; and those with inferior visual skills can be employed productively rather than be denied employment based on rigid arbitrary standards. With periodic testing, losses in visual skills are disclosed and their correction may be accomplished before production or safety is affected. The increased demand for the services of an ophthalmologist is also mentioned.

Two methods of segregating workmen and making statistical compari-

son of their visual skills are used: (1) "Follow-up" method in which all new employees on a specific job are tested and the results tabulated for future analysis; (2) the testing of present employees on a job, classifying them on the basis of quantity and quality of production. The results of such investigations make possible appraisal of the visual requirements of any specific position.

Chas. A. Bahn.

Tolman, C. P. **Eye conservation and increased production.** Trans. Amer. Acad. Ophth., 1946, July-Aug., pp. 225-230.

Conservation and utilization of eyesight in industry is a profitable investment. Two out of five workers have visual deficiencies which prevent their best possible work and in 90 per cent of them the vision can be made satisfactory by glasses. Adequate lighting will increase production. A proper color scheme will lessen fatigue, increase production, and increase the efficiency of lighting. Minimal visual requirements should be determined for any specific position and all employees should have a visual test.

Dr. George N. Seidlitz, St. Louis, Missouri, died November 5, 1946, aged 85 years.

Dr. Samuel Anise Shoemaker, Orlando, Florida, died November 6, 1946, aged 80 years.

Dr. Andres Jay Timberman, Columbus, Ohio, died October 15, 1946, aged 82 years.

MISCELLANEOUS

VETERANS' ADMINISTRATION PROSTHESES

The Army's plastic artificial eye has been used by more than 7,500 former soldiers during the past three years and has been adopted by Veterans' Administration in furnishing ocular prostheses to patients, the War Department announced recently.

Developed first in 1943 by a former major in the Army Dental Corps while stationed in England, this type of acrylic eye has practically replaced glass eyes which were used almost exclusively before World War II. The Army Medical Department developed this eye after the war broke out, when both civilian and military supplies of artificial eyes were depleted due to high breakage and inability to replenish supplies. Glass eyes then used in the United States were largely German-made.

As early as 1943, the Army made plans to discard the easily breakable, inferior, custom-made glass eye when Major (then Lieutenant) Stanley F. Erpf of San Francisco, California, assigned to the job by Col. Derrick T. Vail, Consultant in Ophthalmology in ETO, successfully demonstrated the artificial eye made of water-clear plastic and individually fitted and colored. In January, 1944, the first training center for ophthalmoprosthetists was organized at the 30th General Hospital, England. Forty American dental officers and 10 British dental officers attended.

Dr. Robert E. Stewart, Chief, Ophthalmoprosthetic and Restoration Division, Prosthetic Appliance Service, Veterans' Administration,

said today that all 15 technicians making artificial plastic eyes for Veterans' Administration are Army-trained. They were dental officers and technicians especially trained in this work during the war.

"The Army-developed artificial eye has proved superior to any other type of ocular prosthesis available today," Dr. Stewart declared. "Of about 500 World-War II veterans who have applied to the Veterans' Administration for ocular prosthesis aid, none had any serious complaint about the acrylic eye. They wanted lost eyes replaced, socket corrections, or needed refitting because of other operations."

Dr. Stewart said the Army-developed eyes were never broken when dropped nor had the coloring in the eyes deteriorated. He explained that some eyes had become roughened due to hard usage, but this was easily remedied.

SCHOLARSHIP FUND ESTABLISHED

The Delta Gamma fraternity, an international organization of college women, announces the establishment of a fund for scholarships in the fields of Prevention of Blindness and Sight Conservation exemplified by specialized prevention study, training of orthoptic technicians, training of teachers for sight-saving classes, and training of workers for the preschool blind.

Information on basic qualifications for the various fields will be sent upon request. Application blanks may be obtained from Mrs. Richard P. Miller, 39 West Jefferson Road, Pittsford, New York.

Advising the fraternity's council and project committee in the selection of candidates and administration of the fund is a professional committee consisting of: Dr. LeGrand Hardy, Chairman, president of the American Orthoptic Council; Mrs. Virginia S. Boyce, administrative assistant, National Society for the Prevention of Blindness; Miss Ruth E. Lewis, professor of social work, George Warren Brown School of Social Work, Washington University; Miss Ruth B. McCoy, assistant director, New York State Commission for the Blind; Dr. Lillian Ray Titcomb, president, Executive Committee, Nursery School for Visually Handicapped, Los Angeles.

SOCIETIES

READING SPEAKER

The Reading Eye, Ear, Nose, and Throat Society, Reading, Pennsylvania, had as speaker

for the January meeting, Dr. Benjamin F. Souders, whose topic was "Some Recent Developments Regarding Enucleation. Modern Implants and Prostheses, with Particular Reference to the Cutler and Reudemann Techniques."

MILWAUKEE MEETING

The annual meeting of the Milwaukee Ophthalmic Society was held on January 28th. Dr. Erwin E. Grossman of Milwaukee was the ophthalmic speaker. His paper, "Gonioscopy and Glaucoma," was the thesis he presented for membership in the society. Dr. J. B. McBean of the Mayo Clinic spoke on "Observations in the Management of Vasomotor Rhinitis."

TEXAS SOCIETY OFFICERS

At the December meeting of the Texas Society of Ophthalmology and Otolaryngology held in Dallas, Dr. W. E. Vandevere, El Paso, was elected president; and Dr. E. D. Dumas, San Antonio, was elected secretary. The next annual meeting of the society will be held at Houston in December, 1947.

WASHINGTON GUEST SPEAKER

The Washington, D.C., Ophthalmological Society had as guest speaker for the January meeting, Dr. Charles E. Iliff of the Wilmer Institute, Johns Hopkins University. He spoke on "Beta Irradiation in Ophthalmology."

A case presentation was given by Dr. M. Noel Stow on "Pseudoxanthoma Elasticum with Angioid Streaks: The Syndrome of Groenblad and Standberg." Two case presentations were given by Dr. Ralph N. Greene, Jr.; one on "Possible Tumor of the Macula," the other on "Multiple Cholesterol Deposits of the Retina." Dr. Edward J. Cummings spoke on "Epithelioma of the Lid," and Dr. A. J. Delaney spoke on "Pigment Proliferation or Benign Melanoma."

ANNOUNCEMENT

OREGON POSTGRADUATE COURSE

The Oregon Academy of Ophthalmology and Otolaryngology announces its eighth annual spring postgraduate course to be held in Portland, April 7 to 12, 1947. A fine program has been arranged by the Oregon Academy and the University of Oregon Medical School.

Dr. John Dunnington, professor of ophthalmology at Columbia University, New York, and Dr. George Shambaugh, professor of otolaryngology at Northwestern University Medical School, Chicago, will be the guest speakers.

There will be lectures, clinical demonstrations, and ward rounds. In order to make the course more personal and practical, registration will be limited to 125. Further information may be obtained from Dr. Harold M. U'ren, secretary, 1735 North Wheeler Avenue, Portland 12, Oregon.

PERSONALS

During February, Dr. Arthur Links continued the series of lectures and demonstrations on "Physiological and Geometrical Optics," at the Manhattan Eye, Ear, and Throat Hospital, New York.

Ben A. Ramaker and Ivan L. Nixon have been appointed managers of the Bausch & Lomb Optical Company's ophthalmic and instrument divisions. Raymond H. Andersen was named to succeed Ramaker as head of the company's ophthalmic sales, and Lysle B. McKinley was appointed successor to Nixon as manager of the firm's instrument sales division.

Dr. Trygve Gundersen has been appointed assistant professor of ophthalmology at the Harvard Medical School.

Dr. H. Saul Sugar is now located at 2311 David Broderick Tower, Detroit 26, Michigan.

TYPES OF CONGENITAL CATARACT*

THE SANFORD R. GIFFORD MEMORIAL LECTURE

FREDERICK C. CORDES, M.D.

San Francisco

I appreciate very highly the great honor you have conferred upon me by asking me to present the Sanford R. Gifford Memorial Lecture. May this presentation be worthy of that honor.

To have known Dr. Sanford R. Gifford as a scientist, an ophthalmologist, a teacher, and a clinician was an inspiration. His modest, unassuming bearing, combined with his consideration of others, endeared him to all who came in contact with him. To have known "Sandy" Gifford as a colleague, as a companion of the trail, and a campmate at the Bohemian Grove was a rare privilege. Indeed, these memories are among my most cherished.

I have taken as my subject a discussion of the various types of congenital cataracts, a condition that I have been interested in for a number of years. It also seems a particularly appropriate topic because of Dr. Gifford's interest in the subject; he having written three papers on congenital cataracts, two in the American and one in the German Literature. In addition, he and Dr. Latta, in 1923, discussed what is now referred to as retrolental fibroplasia or persistence and hyperplasia of the primary vitreous.

A thorough knowledge of congenital

cataracts is essential for the proper interpretation of slitlamp findings and for an intelligent discussion of the condition with the patient or the patient's parents. Inasmuch as most congenital cataracts are stationary and cause no interference with vision, this knowledge makes it seem wise often not to tell the patient of his condition and thus avoid a great deal of unnecessary worry. This knowledge also permits an intelligent discussion of the prognosis and treatment in cases of the more extensive type of congenital cataract when parents bring their children to the ophthalmologist at an early age. In addition, it is possible in certain instances to assure the parents that in all probability future siblings will not have the same anomaly.

Certain forms of congenital cataracts show an hereditary tendency. These seem to be primarily the dominant type. The type may not always be consistent so that lamellar, polar, spindle, and central cataracts all may occur in the same family. In some instances, however, the type may be the same in all members of the family involved. Haro,¹ for example, observed a family of 59 persons, covering four generations, in which 16 members had ring or disc-shaped cataracts. Atypical forms have been observed through several generations.

It is noteworthy that in 50 percent of the cases of congenital cataract other ocu-

lar disturbances are present. These include strabismus, amblyopia, nystagmus, aniridia, choroidal and retinal changes, microphthalmus, and other anomalies.

With the introduction of the slitlamp and corneal microscope, our knowledge of congenital cataracts has been enriched by

As pointed out by Ida Mann,² a certain number of congenital abnormalities can be explained as abnormal persistences of a normally transient condition. But it must also be borne in mind that a greater part of so-called developmental anomalies do not represent any normal stage, but

Fig. 1 (Cordes). Section through the eye of a 7- to 8-mm. human embryo (four weeks). The fetal fissure is still open, and the lens vesicle is still connected to the surface. Cells of the posterior wall of the lens vesicle are beginning to elongate. The so-called "epitrichial" cells are enclosed in the lens vesicle.

the systematic study of the lens as seen with the widely dilated pupil. Thus, we know that there are many fine congenital cataracts that were unknown to older observers, and which are only visible to us now because of the slitlamp. A clear lens, one in the sense of a good photographic or microscope lens, is probably nonexistent in the human eye, as practically all lenses, even those of young children, show some punctate or dustlike opacities. How many of these opacities were present before birth and how many may have developed in the first few years of life is naturally a difficult thing to judge.

are pure aberrations of growth. The most that can be said in regard to the production of these developmental anomalies is that it is possible to deduce from their location and to place accurately the time at which the fibers involved were formed. Whether the opacities occurred at this initial time or whether they occurred as the result of a subsequent degeneration, it is impossible to say.

EMBRYOLOGY OF THE LENS

Some knowledge of the embryology of the lens is necessary for a proper understanding of the biomicroscopy of the

lens. The lens arises from ectoderm. In a 4.5-mm. human embryo Ida Mann³ was able to identify the lens plate. According to Ida Mann⁴ this formation is followed by a symmetrical indentation of the lens plate to form the lens pit. This in turn invaginates to form the lens vesicle which is complete by the 7- to 8-mm. (fig. 1)

sure is still open (fig. 2). The primary lens fibers now fill half of the lens vesicle. At the 18-mm. stage (7 weeks) the fetal fissure is closed and the cavity of the lens vesicle is almost filled. The hyaloid artery and the tunica vasculosa are present at this stage. By the 26-mm. stage (8 weeks) the primary fibers are complete (fig. 3).

Fig. 2 (Cordes). Section through the eye of a 10-mm. (five weeks) human embryo. The lens vesicle has separated from the surface. Further elongation of the cells of the posterior wall is evident, and there is a decrease in the enclosed epitrichial cells. The hyaloid artery is present and the tunica vasculosa lentis is beginning to appear.

stage; however, the vesicle is still connected to the surface. The primary lens fibers now begin to form from the cells of the posterior wall. It must be remembered that the whole adult lens is formed from the cells of the posterior wall and the equatorial region, the anterior wall of the lens vesicle taking no part in the formation of lens fibers. During this stage, the tunica vasculosa lentis also begins to form. By the time the 10-mm. stage (5 weeks) has been reached, the lens vesicle is separated from the surface but the fetal fis-

These primary fibers remain at the exact center of the lens throughout life, and form the embryonal nucleus. Where these fibers come in contact with the fibers from the opposite side they form the lens sutures, the anterior erect Y and the posterior inverted Y. During this time the lid buds also make their appearance. In the 65-mm. stage (11 weeks), we find that the embryonic nucleus is now surrounded by the secondary lens fibers. Bowman's and Descemet's membranes are also present in the cornea, and the lids have formed.

The secondary fibers continue to form throughout life by division of cells of the equatorial region. The complicated pattern of sutures causes these fibers to become closely merged. These patterns differ and their surfaces possess slightly different indices of refraction, so that, by using the slitlamp, the various stages of

of this elaborate vascular system surrounding the lens atrophies and disappears between the seventh and ninth months, but remnants of it can often be seen even in old age in a large number of people. The anterior part, or pupillary membrane, persists relatively late. Ida Mann⁵ described this as seen both in sec-

Fig. 3 (Cordes). Section through the eye of a 30-mm. embryo. The formation of the primary lens fibers is complete, and the embryonic nucleus is formed. In the equatorial region, the secondary fibers are forming. The anterior chamber is present, and the tunica vasculosa is complete. The lid buds are present.

development can be determined (fig. 4).

The tunica vasculosa lentis is a capillary network that surrounds the lens during its development. It is derived from the hyaloid artery and appears during the fifth week. As the hyaloid artery develops, it branches throughout the primary vitreous to form the posterior part of the tunica vasculosa lentis. The central part of the network is formed from vessels that come in from the upper edge of the optic cup and from the equatorial portion. The anterior part is derived from the vascular system of the iris. Practically the whole

tion and as it appears in fetal eyes of five to nine months as observed with the slitlamp. The failure of this atrophy may have a bearing on retrolental fibroplasia.

Any arrest of development causes changes in the lens. Those changes occurring before the fourth week are more profound, and the result is gross abnormalities of the eye itself. Those changes that occur between the fourth and sixth weeks result in gross abnormalities of the various structures of the eye. Mann⁶ states that delay of closure and separation of the lens vesicle from the surface ectoderm

permits the lens fibers to grow forward and protrude through the opening in the capsule with a resultant anterior-capsular opacity. The failure of the development of lens fibers from the cells of the back wall of the lens vesicle leads to an absence of the central portion of the lens and results in the formation of a congenital disc-shaped cataract.

portion of the lens that is formed before the third month.

2. *Fetal nucleus* is the term applied to the zone between the embryonic nucleus and the next reflecting surface. This nucleus begins to be formed in the third month and is formed during intrauterine life.

3. *The adult nucleus* is enclosed by the

Fig. 4 (Cordes). Sagittal section through the eye of a 65-mm. (11 weeks) embryo. The embryonic nucleus is surrounded by the developing secondary fibers. The cornea with Bowman's and the beginning of Descemet's membrane is present. The formation of the lids is complete.

The diagnosis of congenital cataracts is to a great extent dependent upon biomicroscopy of the lens. With the fine beam of the slitlamp and the corneal microscope, the suture lines and certain surfaces representing stages in the development of the lens are visible throughout life. Four zones can easily be differentiated.

1. *Embryonic nucleus*. This is the central layer between the Y sutures and is the

next reflecting surfaces and will later become the lens of adult life. It is formed during adolescence and early adult life.

4. *A cortex* covering these various strata and consisting of fibers laid down in later life forms the next layer which is its largest in old age.

These layers are covered by the lens capsule and anterior epithelium. Just nasal to the posterior pole of the lens the hyaloid artery attaches itself for a time to the

lens capsule and sends branches over its surface (tunica vasculosa lentis). At 8½ months it disappears, but persists as a corkscrewlike thread (hanging into the vitreous) which may be seen with the slit-lamp in adult life. At times its attachment

Fig. 5 (Cordes). Anterior axial embryonal cataract.

may be seen with the ophthalmoscope as a fairly large dot, the posterior lens dot, and is sometimes referred to as a posterior-lens cataract. This form does not interfere with vision as it is always located slightly nasal to the posterior pole.

During life, the lens continues to increase in size by the growth of new lens fibers from the cells just beneath the capsule, which are the only ones to retain their nuclei. These fibers are in turn displaced centrally by the development of other new fibers. Thus the subcapsular opacity left by an injury to the lens received in childhood is found in adult life to be located in the deeper layers of the lens and the period at which such an injury occurred can be determined rather accurately with the slitlamp.

CONGENITAL LENS OPACITIES

ANTERIOR AXIAL EMBRYONAL CATARACT

This is the most frequent form of congenital cataract. According to Vogt⁷ it occurs in approximately 25 percent of all individuals. The cataract consists of multiple fine opacities that are irregular in form and lie in close proximity to the anterior embryonal suture and usually at its exact level. In direct light these opacities appear as white, chalklike bodies which on occasion may have a crystalline appearance. The opacities are surrounded by a faint halo, and are usually multiple although they can occur as single opacities (fig. 5). They cause no interference with vision and, like all congenital cataracts, are stationary. The formation of this type of cataract probably occurs in the fourth embryonal month. Vogt⁷ says: "It is conceivable that the opacity has its origin in an early stage in which the cavity of the lens vesicle was becoming obliterated and the included cells were not absorbed." Ida Mann⁸ does not feel this is likely since any cell remnants in the cavity of the lens

Fig. 6 (Cordes). Stellate (sutural) cataract involving the anterior Y.

vesicle would be present either immediately under the anterior capsule or, conceivably, somewhere in the line of the anterior embryonic suture, but not behind or to either side of this. It is noteworthy that the anterior embryonal cataract is the only form of cataract that does not occur symmetrically in the anterior and posterior half of the lens.

STELLATE (SUTURAL OR TRIRADIATE) CATARACT

Vogt⁹ was the first to demonstrate that these congenital sutural cataracts occur in either the anterior or posterior suture, but more frequently the posterior (fig. 6). The sutures appear as white, thick lines extending as far as the branching and are accompanied by a varying-sized zone of opacification that is blue-green in color. The reverse color arrangement can also occur. These colors, which are also present in cataracta cerulea, are caused by the varying thickness of the opacities, the thinner having the greater tendency to the blue tint. Very thin opacities which are not visible in reflected light, appear blue-green in direct light in contrast to the yellowish lens. If these opacities are denser, they appear white. On rare occasions these clouded sutures appear in layers. This unusual condition is explained either by recurrent damage during the developmental stage or through the interposition of newly formed lens fibers. Duke-Elder¹⁰ believes that the stellate cataract develops subcapsularly during intrauterine life, probably about the time of birth. These cataracts are stationary, but the larger ones may interfere with vision.

PUNCTATE CATARACT (CATARACTA PUNCTATA)

Scattered small gray or light blue opacities are found in the extreme periphery of most young lenses. When these

opacities are scattered throughout the lens without involving the embryonal nucleus, they are called punctate cataract. This cataract must be differentiated from cataracta coronaria which may begin with light blue opacities in the equator of the

Fig. 7 (Cordes). Punctate cataract in which the opacities are scattered throughout the lens without involving the embryonal nucleus.

lens. According to Duke-Elder¹¹ an almost identical type occurs in Mongolian idiocy, in which condition it usually develops about puberty. True congenital punctate cataracts are very rare and may be associated with stellate cataract. Collins¹² felt that the opacities represent late-formed fibers which have undergone degeneration and have broken down into granular debris, and have then subsequently been surrounded by healthy fibers (fig. 7).

CONGENITAL OPACITIES AT THE ANTERIOR POLE OF THE LENS

Bellows¹³ classifies the congenital opacities of the anterior pole of the lens into three groups: (1) Anterior or pyramidal (central punctiform) cataract. (2) Capsular flakes. (3) Circular cataract.

1. *Anterior polar or pyramidal (central punctiform) cataract.* This cataract (fig. 8) consists of a sharply circumscribed opacity of the anterior lens capsule. The opacity varies greatly in size from pin-head to an opacity that may fill the pu-

lar form may follow small perforations of the cornea.

2. *Capsular flakes (Vogt-kapselstarflecken).* Meesmann¹⁵ states that capsular flakes consist of white, oval or round, sharply circumscribed dense opacities that may be up to 1 mm. in size (fig. 9). They are frequently found associated with deeper opacities. The number of opacities varies but they are usually multiple. These opacities may appear as flat prominences on the capsular surface which, as Vogt¹⁶ pointed out, make the affected area lose its normal shagreen when examined with the slitlamp. Pigment threads or star-shaped pigment debris are frequently found in the area of the opacities. Inasmuch as the opacities are rarely axial, they cause no visual loss.

3. *Circular capsular or subcapsular cataract.* As stated by Bellows,¹⁷ circular capsular or subcapsular cataracts have been reported a number of times. The opacities vary in color from white, bluish white to "slightly brownish" in Gifford's¹⁸ case. The opacities may be round or radially placed. Pigment deposits and persistent pupillary membrane may also be present. In Gifford's case the opacity was

Fig. 8 (Cordes). Anterior polar (pyramidal) cataract.

pillary area. It is often laminated and is a conical projection in many instances, being sometimes directed toward the nucleus but usually projecting above the lens. According to Jess¹⁴ there may at times be a fine thread connecting the opacity to the cornea. This type of cataract is easily recognized by parents who then bring their children to the ophthalmologist. Not infrequently fine lines radiate from the opacity, and the cortex beneath may also be involved. The visual loss is dependent upon the size of the opacity; if this opacity is rather large, vision may be much better in dim light. Like most congenital cataracts the condition remains stationary in most instances, although Jess¹⁴ states that cases have been reported in which the opacity progressed to complete opacification. A simi-

Fig. 9 (Cordes). Capsular flakes.

circular-and subcapsular and measured 1.5 to 2 mm. in diameter. The opacities were closest to the capsule at the periphery and in the center showed a "depression like the crater of a volcano." The vision may be surprisingly good, and was found to be 20/30 in Gifford's patient (fig. 10).

REDUPLICATION CATARACT

The development of this interesting form of anterior lens opacity has been described by Ida Mann.¹⁹ This condition shows that there has been an intrauterine or, more rarely, postnatal injury or defect of the anterior capsule together with involvement of a few of the lens fibers which were in direct contact with it. The lens fibers laid down after the initial disturbance may be relatively normal and may grow between the degenerated portion of the cortex and the capsular changes. This process results in a localized opacity of the anterior capsule with a similar opacity below it, but separated from it by normal lens substance. It is possible to place the time of the

original aberration by the depth of the reduplication from the lens surface (fig. 11).

POSTERIOR POLAR CATARACT

The posterior lens dot representing the remnant of the attachment of the hyaloid

Fig. 11 (Cordes). Reduplication cataract.

artery is very common. At times there may be a large dense circular opacity covering the posterior pole, which represents a persistence of the fibrovascular sheath of the lens. Duke-Elder²⁰ feels that this condition can not legitimately be called a true cataract. A disturbance of the lens fibers directly beneath this may follow and in this way a localized posterior opacity may be formed corresponding to the anterior polar cataract. The opacity is confined to the capsule and the cortex just beneath it but it often causes marked interference with vision. When both eyes are affected, removal of the lens is indicated. Because of the fact that other anomalies are often present the prognosis must be guarded when surgery is considered.

Fig. 10 (Cordes). Circular capsular or subcapsular cataract. (Reconstructed from Gifford. *American Journal of Ophthalmology*, 1924, volume 7, September, page 678).

POSTERIOR LENTICONUS

Posterior lenticonus is a rare anomaly in which there is a conical or globular protuberance on the posterior lenticular surface. Von Szily²¹ states that in addition to those cases in which there is an abnormal development of the posterior pole of an otherwise normal lens, there are some cases that are undoubtedly associated with the rupture of the posterior capsule. Vogt²² found that 80 percent of the cases reported were complicated by pos-

type that occurs within the first year of life. This cataract consists of a zone of lamellar opacities surrounding a clear, or almost clear, zone in the manner in which an orange peel surrounds the fruit. This zone of opacity is surrounded, in turn, by clear cortex. It is now a generally accepted fact that the opacity may occur either as a prenatal or a postnatal development. The size of the opacity varies and is dependent upon the state of development at the time of the lens damage; the earlier the disturbance the smaller the opacity. If involvement takes place at an early stage, the embryonic nucleus is surrounded by the opacity, but if it takes place during the last four months of pregnancy, the opacity will be within the fetal nucleus. Where opacification takes place after birth, the zone of the opacity will just surround the fetal nucleus.

The cataract appears as a round, gray, uniform opacity surrounded by a clear dark zone. It may be composed of fine white dots which according to von Szily²⁴ suggest a possible relationship to cataracta pulverulenta. There are thick, gray, radially placed U-shaped opacities, consisting of an anterior and posterior limb, that saddle the cataract in the equatorial region. At times, only part of the lens may be involved. Other parts of the lens may also be involved so that there may be fine punctiform opacities and opacification of the embryonic sutures. In addition, there may be a central embryonic nuclear opacity within the zonular opacity. At times there may be blossomlike opacities in the anterior portion of the cataract. The opacities have a tendency to increase in density rather than size and usually become stationary between 32 and 55 years of age. The size of the opacities has been given as between 5 and 8 mm. by von Bahr,²⁵ while von Szily²⁶ gives the figures as 2 to 8 mm. Von Arx²⁷ states that the thickness of the opacities varies between 0.5 and 0.7 mm.

Fig. 12 (Cordes). Zonular (lamellar) cataract.

terior lens opacities, and, while persistent remnants of the hyaloid artery were by no means uncommon, they were situated slightly to the nasal side of the apex of the conus. The central part of the lens becomes highly myopic and causes dimness of vision. With the slitlamp, a ring reflex is seen which is often associated with a remnant of the hyaloid artery.

ZONULAR (LAMELLAR) CATARACT

According to Jess²³ the zonular cataract (fig. 12) is one of the most frequent types of congenital cataract if we include the

There is a marked hereditary tendency, inheritance being usually of the dominant type. The condition is nearly always bilateral and there is, as a rule, equal involvement of the two eyes. The vision varies between hand movements and 20/30, depending upon the size of the opacities.

In some of the congenital cases, the disturbance continues until birth, or is so unusually severe that the entire lens may be opaque. Under these conditions further growth of the lens fibers does not take place. This type is usually associated with other congenital defects of the eye, and any operative prognosis must be guarded.

Bellows²⁸ classifies zonular cataracts into three groups: (1) The congenital type showing an hereditary predisposition. (2) The type associated with tetany, appearing either in the first years of life, or originating later in life as a result of parathyroid deficiency. (3) A form resulting from local eye disease or trauma.

1. *Congenital type.* It has been frequently demonstrated that zonular cataracts may be congenital and may show marked hereditary or familial tendencies. The transmission of the cataracts is continuous, only those individuals having the anomaly transmitting it; and it is transmitted by either sex and is not sex limited. Bellows²⁸ feels that the most probable explanation of formation is the possible occurrence of convulsions in the mother or fetus, as hypocalcemia or even tetany are not unknown in pregnancy. In addition, the formation of these cataracts may be related to the greater demand for calcium during the last three months of intrauterine life.

2. *Type associated with tetany.* This is the most common type of zonular cataract and its association with convulsions during the first year of life has been an established fact for many years. Although rickets was at one time considered the

causative factor, tetany, has been established as the primary etiologic factor in the cataract development.

3. *Resulting from local disease or trauma.* The cataract has also often been observed after iritis, perforating corneal ulcer, contusions, and perforating injuries. Jess²⁹ reported the condition in a 13-year-old girl who, in the second year of life, had had a perforating injury with a needle.

As Hess³⁰ and others have pointed out,

Fig. 13 (Cordes). Embryonal nuclear cataract (cataracta centralis pulverulenta).

it must be remembered that the etiology of these lens opacities is not always the same. It must also be remembered that tetany can cause nuclear, cortical, or total cataract.

If the opacity too greatly interferes with vision, surgery is indicated for these cases and linear extraction seems to be the chosen operation. In cases where there is a presence of nystagmus, one must give a guarded prognosis as to vision.

EMBRYONAL NUCLEAL CATARACT (CATARACTA CENTRALIS PULVERULENTA)

Poos³¹ and others believe that this cataract is related to the zonular cataract

for, even though it is smaller, the characteristics of zonular cataract may be present. Gifford³² also felt there was some relationship between this form and coraliform cataracts. The cataract consists of a fine gray-white opacity (fig. 13) lying between the anterior and posterior Y sutures, the embryonal nucleus. This fact makes it apparent that the disturbance occurred in the first three months of intrauterine life. The opacity is seen as a small gray globe in the otherwise clear lens. Under the slitlamp, its appearance has been described as resembling particles of dust seen in the sunshine. The condition is usually bilateral with a tendency for similar involvement in the two eyes. The condition is usually stationary, and the opacity measures 1.5 to 2.0 mm. The opacity may be rather dense. There is also a definite hereditary tendency. Nettleship and Ogilvie³³ found the condition in 20 members of one family. The cataract causes little interference with vision and Gifford³⁴ states that "operation is never required for opacity limited to the embryonal nucleus." Jess³⁵ observes that the embryonal nuclear cataract is often found in combination with the zonular cataract.

TOTAL CONGENITAL CATARACT

According to Jess³⁶ this is a relatively rare form of congenital cataract. Hess³⁰ feels that it differs from the embryonal nuclear cataract and the zonular cataract only in that a larger portion of the lens is involved. In addition to complete opacification, there are some cataracts in which a small portion of the lens may remain relatively clear. At times there may be a shrunken cataract. Usually both eyes have the same degree of involvement, although, at times, one eye may have a total cataract and the other a membranous type. Total cataracts have been observed that did not become entirely opaque until after birth. Particularly in those cases where there

has been a proliferative process of the tunica vasculosa, there is a tendency for later cataract development. The cataract may degenerate to the point of liquefaction so that it resembles a hypermature Morgagnian cataract. Even though the changes have taken place in intrauterine life, Mann³⁷ feels that the cause is probably a metabolic one which occurs near the end of fetal life.

MEMBRANOUS CATARACT

Jess³⁸ states that these cases are genetically related to total cataract. With absorption of the lens parenchyma during intrauterine life, the anterior and posterior capsule collapse to form a thin gray-white or chalky-white membrane. The presence of a deep anterior chamber associated with iridodonesis helps to make an easier diagnosis. The condition is frequently bilateral and often associated with other anomalies and with nystagmus and strabismus. In some cases there has apparently been an intrauterine iritis. Congenital lues has also received consideration as an etiologic factor. In a few cases the rupture of the posterior capsule has been demonstrated. While the condition is usually not considered to be hereditary, I have seen three members of one family with the same condition. In each case dissection of the membrane resulted in useful vision, although all three had nystagmus.

FLORIFORM CATARACT

In 1923 Koby³⁹ described a rare form of congenital cataract to which he gave the name floriform (fig. 14). The opacity takes the form of annular elements, arranged either independently or grouped together like the petals of a flower. They are most commonly found in the axial portions of the lens, especially in the region of the fetal sutures. The condition shows a familial tendency, Koby report-

ing one family in which the mother and four children were affected. According to Meesmann⁴⁰ the opacities which are not visible in direct light are bluish-white to yellow as seen with the slitlamp.

AXIAL FUSIFORM CATARACT (SPINDLE CATARACT)

This cataract (fig. 15) was first described by Knies⁴¹ in 1877. The usual type consists of anterior and posterior polar cataracts united by threadlike opacities extending axially through the lens. According to Jess⁴² sometimes only the anterior or posterior part of the spindle may be present. The degree of interference with vision varies according to the amount of opacification present. The fusiform cataract is usually bilateral and the two eyes show equal involvement. This

strated by Collins⁴³ and others. Duke-Elder⁴⁴ feels these cataracts result from some disturbance in early fetal life which affects the axial area of the lens and inter-

Fig. 15. (Cordes). Axial fusiform cataract (Spindle Cataract).

feres with the growth of new lens fibers in this region.

CORALLIFORM CATARACT

Coralliform cataract was the name given by Gunn⁴⁵ in 1895 to this unusual type of hereditary cataract. He described the cataract as composed of "rounded and oblong grey and white opacities seen grouped toward the center of the lens, so as to resemble a piece of coral growing forwards and outwards from this point." The condition has also been described by Nettleship,⁴⁶ Gifford,³² and others. In 1937 (fig. 16), Gifford and Puntenney⁴⁷ reported another case in which "irregular stellate or flower-shaped opacities extended forward to the anterior capsule and backwards to the posterior capsule, being connected with similar branching opacities involving all the layers of the lens in the axial area." The condition has a definite hereditary tendency, Nettle-

Fig. 14 (Cordes). Floriform cataract. (Drawn from Bellows. *Cataract and Anomalies of the Lens*, St. Louis, C. V. Mosby Co., 1944, page 274).

type of cataract shows a definite hereditary tendency. Embryonal nuclear, lamellar, and axial fusiform cataracts have been observed in the same family. An actual adhesion of the nucleus to the anterior and posterior capsule has been demon-

ship⁴⁶ having found 35 persons involved in five generations of one family.

Verhoeff⁴⁸ examined one of these lenses microscopically and found large masses of

Fig. 16 (Cordes). Coralliform cataract. (From Gifford and Puntteney. *Archives of Ophthalmology*, 1937, volume 17, page 885).

crystals surrounded by areas of alterations in the lens fibers. The crystals consisted of rectangular and rhombic plates which showed the microchemical reaction of protein. These findings were confirmed by a case of Zentmayer's.⁴⁹ Nettleship assumed these cataracts to be identical in nature with spindle or fusiform cataract. Verhoeff⁴⁸ however, feels that the striking coral-like appearance and the distinctive crystals favor the opinion that the condition is entirely distinct from spindle or fusiform cataract. More recently, Mann⁵⁰ has grouped them all together and states that the axial fusiform cataract may arise by undue adhesion of the primary lens fibers to the anterior and posterior capsule while coralliform cataract involves the earliest secondary lens fibers which, failing to meet to form the anterior suture, remain wide open.

SPEAR CATARACT

Vogt⁵¹ described a type of cataract that he called "spear cataract" (fig. 17). In his case, spiky, branching opacities were seen running through the axial portion of the lens with no apparent relation to its anatomic structure. In places these opacities resembled insects; in other places the needlelike opacities showed a play of colors. In some instances, the crystals measured a millimeter in length and were arranged in bundles similar to tyrosine crystals. One lens which was extracted showed a predominance of cystein on chemical analysis. Gifford¹⁸ had a similar case in which the opacities were more regularly arranged so that they had the appearance of "two conventional fir trees placed base to base, the bases occupying the center of the lens." In 1937 Gifford and Puntteney⁴⁷ reported a case (fig. 18) in which the opacity was composed of crystals which resembled those of a spear cataract but were arranged in a more compact and circular mass. The central mass was just anterior to the anterior Y. A thin layer of cortex was present anterior to the outer zone of the crystals. The crystals were

Fig. 17 (Cordes). Spear cataract of Vogt. (Drawn from Vogt, A. *Archiv für Ophthalmologie*, 1922, volume 107, page 237).

those of calcium sulfate. Gifford³² feels that these are all varieties of the congenital axial group of cataracts and states⁴⁷ that the reports indicate that chemical changes may occur in lenses belonging to the coraliform group that result in the formation of crystals in the lens.

SPIROCHETELIKE CATARACT

Koepp⁵² reported in 1921 an unusual type of congenital cataract that was bilateral and had fine lens opacities scattered through the lens. In the adult nucleus were some radiating opacities. The posterior pole showed an ill-defined disciform, conical opacity with its blunt tip directed toward the nucleus. In this area of the lens were numerous spirochetelike or corkscrewlike gray opacities that varied in size and thickness. During a 4½-year period of observation no change could be discerned (fig. 19).

DISC-SHAPED OR RING CATARACT

This rather rare and unusual congenital cataract, resulting from the absence of the

embryonic nucleus, has been described by Riedl,⁵³ Vossius,⁵⁴ Collins,⁵⁵ von Szily,⁵⁶ and others. The cataract consists of a depressed opaque central area surrounded

Fig. 19 (Cordes). Spirochete like lens opacities. (Modified drawing from Koepp, L. *Klinische Monatsblätter für Augenheilkunde*, 1922, volume 69, page 482).

Fig. 18 (Cordes). Opacities composed of crystals resembling the spear cataract. (From Gifford and Puntteney. *Archives of Ophthalmology*, 1937, volume 17, page 885).

by a clear lens of normal size and thickness and forms a closed ring that has been described as resembling a life preserver (fig. 20). The depressed area in the center is not a hole, and there is no free communication between the anterior and posterior chamber. The central defect varies in size but never exceeds the diameter of the embryonic nucleus. In section, it appears as a dumbbell, having two lateral masses connected by a central band. In the pathologic examination of Haro's case⁵⁷ "the lens resembled a doughnut with a central, thinned, membranous area, 2.5 to 3 mm. in diameter, which was grey-white. The surrounding ring structure possessed the body of lens substance but showed yellowish opacities extending from the membranous portion toward the equator." In section the central area representing the axial portion was reduced to a membranous band about 0.5 mm.

thick, composed anteriorly of an intact, folded glass membrane. "A wavy glass membrane could be followed along the posterior surface from each outer margin but appeared to be absent or poorly formed centrally. Between these two membranes was a groundwork of a pale

Fig. 20 (Cordes). Ring (disc-shaped) cataract (Modified drawing from von Szily, *Klinische Monatsblätter für Augenheilkunde*, 1928, volume 81, page 145).

eosinophilic, slightly fibrillar mass, in which could be found fusiform cells occurring in clumps."

While the lens substance within the ring is usually clear, there may be a zone of opacification resembling a zonular cataract.

There is a definite hereditary tendency in this condition; von Szily⁵⁶ has reported a family in which four members were affected. Haro⁵⁷ observed a family of 59 individuals covering four generations in which 16 members had congenital cataracts. In all members examined the cataract was of the disc-shaped type. Of this cataract, Ida Mann⁵⁸ says that the most logical embryologic explanation is that the nucleus, having failed to develop, shrinks

and calcifies and remains adherent to the capsule so that the outer fibers cannot grow around it but merely plaster themselves to the equatorial region. However, the initial cause is still unknown.

Aside from the congenital, familial disc-shaped cataract, there is another form described by Vossius,⁵⁴ Goldfeder,⁵⁹ Marchesani,⁶⁰ Wessely,⁶¹ and others; this is the so-called Soemmerring's ring. These cataracts may follow discission, corneal perforation, and, above all, perforating ulcers. The damage to the capsule must occur in the center of the lens during youth when the nucleus is still absorbable.

There are various surgical treatments for these cases. In many of these cases where the remainder of the eye is normal, a discission of the central membrane is usually sufficient. Collins,⁴³ in one case, was able to separate the central plaque, which fell into the anterior chamber where it remained without reaction. In two of his cases, Haro⁵⁷ found the membrane so tough that it was necessary to make a keratome incision and cut the central membranes with de Wecker scissors. Total extraction must be considered with caution because of the fact that in some of these cases the central plaque is adherent to the hyaloid membrane.

CONGENITAL CATARACT AFTER RUBELLA (GERMAN MEASLES) IN THE MOTHER

In May of 1944, Reese⁶² reported three cases of congenital cataracts in infants born of mothers who had rubella in the first month of pregnancy. This report followed the original ones of Gregg⁶³ and of Swan and his co-workers⁶⁴ when an epidemic of rubella in Australia called the prevalence of this condition to their attention. Since that time, over 200 cases have been reported and now the entity is well-established. I have never been able to find one instance of lens abnormalities where

the rubella was contracted after the third month. Typical findings personally observed in a child, aged nine years, suggests that the condition is not a recent one.

In addition to having lens changes, these children are small, ill-nourished, and difficult to feed. A high percentage show

clearer peripheral zone. In the second type, the entire lens is opaque. The process involves all but the outermost layers of the lens and is considered to have begun early in embryonic life.⁶² The condition is usually bilateral; in three cases personally observed, the noncataractous eye showed

Fig. 21 (Cordes). Section of eye of 7- to 8-week-old embryo with history of rubella during the fifth week of pregnancy, showing retardation in development of lens. (Cordes and Barber. *Archives of Ophthalmology*, 1946, volume 36, August, page 135.)

cardiac defects (Gregg's series, 43 percent⁶³ and in Prendergast's series, 40 percent).⁶⁵ There is intolerance to atropine together with an inability to dilate the pupil. These babies are prone to pneumonia and may run a temperature of 105° to 106°F. A fairly high percentage show mental deficiency and microcephaly.

Two main types of cataract are observed. In the first type, there is a pearly-white central opacity with a smaller,

pigment changes in the retina. This has also been observed by Prendergast,⁶⁵ Terry,⁶⁶ and others.

In addition to cataracts, nystagmus, strabismus, corneal opacities, microphthalmus, and glaucoma have also been observed.⁶⁷

Surgical results in these cases have been only fair, one of the problems being an inability of dilatation of the pupil. In microphthalmic eyes the results have been poor.

Not without interest is the microscopic examination of the eye of a 7- to 8-week-old embryo with a history of rubella during the fifth week of pregnancy, as reported by Cordes and Barber.⁶⁸ This lens (fig. 21) showed definite retardation of development and differentiation while the posterior segment was normal. Terry,⁶⁶ in comparing the specimen with those in the Minot Embryological Collection at Harvard, stated that the lens showed the differentiation and size of a 17-mm. embryo, while the differentiation and over all size corresponded to the 19-mm. stage. Ida Mann⁶⁹ substantiated the retardation of the development of the lens. Cordes and Barber⁶⁸ offer, as a possible theory, the limitation of the development of the cataract to the first three months of pregnancy. Needham⁷⁰ has pointed out that the ultrafiltrable viruses can pass through the placenta into the amniotic fluid in man. Erickson⁷¹ mentions the fact that embryonic tissues are particularly susceptible to virus infection. During the first three months Descemet's and Bowman's membranes have not formed to protect the lens vesicle; thus, the toxic agent in the amniotic fluid is able to act fairly directly on the lens during this time. The growth of these barriers after the third month may explain the absence of initial lens changes after that time. Swan^{71-a} reported a 2½-month-old fetus with a history of rubella in the second month. Examination revealed unilateral cataract with lack of closure of the fetal fissure.

PERSISTENCE OF TUNICA VASCULOSA LENTIS

Retrolental fibroplasia (Terry); Persistence of tunica vasculosa lentis; persistence and hyperplasia of the primary vitreous (Reese and Payne)—these and many other terms all apply to an abnormality which, while strictly speaking is not a cataract, is so closely associated with the

lens that it warrants our consideration. The condition has been reported many times in the past as a unilateral lesion found at the time of birth in full-term infants. Gifford and Latta,⁷² in 1923, stated that cases of extensive persistence of the tunica vasculosa lentis were "not very rare." As a result of Terry's work,⁷³⁻⁷⁷ the condition has been called to our attention as an entity consisting of a bilateral lesion of premature infants. The increase of frequency is probably the result of the decrease of infant mortality during the last decade.

EMBRYOLOGY OF THE VITREOUS

To understand the condition, some knowledge of the embryology of the vitreous is necessary. At the 4.5-mm. stage, mesoderm begins to appear in the space between the lens plate and the optic vesicle. This mesoderm starts from the primary vitreous. By the 10-mm. stage the primary vitreous is composed of mesoderm derived from the hyaloid artery and from the mesoderm that enters the cup through the space between the anterior rim of the cup and the lens, together with ectoderm which is composed of fibrils from the lens and the inner wall of the optic cups. At the 13-mm. stage, the hyaline capsule surrounding the lens is completely formed so that the lens no longer contributes to the development of the vitreous. The capsula perilenticularis fibrosa is now formed by condensation of the fibrils adherent to the lens and derived from the lental part of the primary vitreous. During this period the hyaloid artery begins to send branches through the capsula perilenticularis fibrosa to form the tunica vasculosa lentis. This completes the development of the primary vitreous, consisting of ectoderm derived from the lens and retina and of mesodermal vasoformative tissue which has formed the hyaloid artery, the posterior

and lateral portions of the tunica vasculosa lentis. With the development of the secondary vitreous from the retina, the primary vitreous persists as a funnel-shaped area with its wide end at the posterior surface of the lens. The condensation line between the primary and secondary vitreous forms the "wall" of Cloquet's canal.

At the 60-mm. stage (11 weeks) the vessels begin to regress and by 8½ months all vessels except the main trunk have atrophied completely. Toward the end of fetal life the mesodermal part of the vitreous disappears and the permanent vitreous is exclusively ectodermal in origin.

CLINICAL COURSE AND APPEARANCE

The condition, present in 12 percent of all premature babies weighing three pounds or less, makes its appearance 4 to 6 months after birth as a gray-white membrane behind the lens. It may cover the entire lens surface or only part of it (fig. 22). Blood vessels of varying size and number are usually visible. The membrane is densest in the central area and

Fig. 22 (Cordes). Clinical appearance of retrolental fibroplasia.

in some cases thins out to such a point at the periphery that the fundus is visible. Terry⁷⁷ and Reese and Payne⁷⁸ report that very long, narrow ciliary processes which go to the edge of the membrane or

Fig. 23 (Cordes). Pupillary membrane rests (persistence of remnants of anterior part of tunica vasculosa lentis) associated with a case of retrolental fibroplasia.

are free can be seen around the equator of the lens. The condition is almost always bilateral. In one case personally seen, there was a persistent pupillary membrane consisting of the ghost vessels of the anterior part of the (fig. 23) tunica vasculosa lentis. These cases have a tendency to develop cataracts; and glaucoma is also a common finding.

Histologically, the posterior surface of the lens is observed to be covered by a dense fibrous tissue. Frequently, one sees clinically that the ciliary processes are elongated and attached to the connective tissue. This was also noted by Gifford and Latta.⁷² In some cases the central hyaloid artery, in the form of a cord of thread, is seen to extend to the posterior surface of the mass. Microscopically the tissue shows embryonic connective tissue and persistent fetal fibrillar vitreous; the

Fig. 24 (Cordes). Section through lens with retrolental fibroplasia (Dr. T. L. Terry).

fibrous tissue being rather rich in blood vessels (fig. 24).

Detachment of the retina is a fairly common occurrence in these cases. Reese and Payne⁷⁸ felt that the formation of the secondary vitreous plays a role in this condition. If the fibrous strands of the primary vitreous remain adherent to the inner surface of the retina then, when the secondary vitreous forms, the retina may be detached. All degrees of this process may be seen and in some of the cases the entire retina was detached and adherent to the retrolental mass.

Terry⁷⁶ feels that the condition is primarily a persistence of the tunica vasculosa lentis with hypertrophy. Reese and Payne,⁷⁸ on the other hand, look upon the condition as being a persistence in part or in toto of the primary vitreous with or without hyperplasia. They class the above lesion as one of four types of clinical manifestation of the condition. Haden⁷⁹ would seem to support this contention when he says that "toward the end of

fetal life very little of the primary vitreous remains. Sometimes, however, this primary vitreous fails to absorb and the mesodermal part develops into fibrous connective tissue, and a firm triangular, opaque mass is formed behind the lens." He further states⁸⁰ that the size, position, and style of the lesion is influenced by the fetal age at which the normal recession of the primary vitreous ceased.

In the differential diagnosis only two conditions deserve serious consideration; retinoblastoma and pseudoglioma. The nine cases on which Reese and Payne⁷⁸ did X-ray studies were all negative for calcium. Transillumination is good in these cases. The most important diagnostic points include first an opaque mass behind the lens that has an anterior concavity; and, secondly, long ciliary processes that can be seen around the edge of the lens. In addition, the history of most cases shows a premature birth. In most instances the lesion is bilateral.

Surgery and radiation have both been

employed in these cases but the results have been very unsatisfactory.

ENCEPHALO-OPHTHALMIC DYSPLASIA

Krause⁸¹ recently presented 18 cases under the title of congenital encephalo-ophthalmic dysplasia. The ocular disease was similar to, or identical with, retrolental fibroplasia of Terry or the persistence of the primary vitreous of Reese and Payne. This dysplasia was more commonly found in premature infants and in infants from a multiple birth. The common neurologic signs were mental retardation, microcephalus, and hydrocephalus. Clinically, the ocular disease rarely occurred without neurologic signs of involvement of the brain when the child was examined after the age of four years.

The ocular signs were loss of vision, ptosis, endophthalmos, microphthalmos, strabismus, retinal detachment, retrolental masses, retinal atrophy and gliosis, retinal dysplasia, coloboma of the choroid and optic nerve, recurrent hemorrhages in the retina and vitreous, secondary glaucoma, and cataract.

Reese⁸² in the discussion of Krause's paper felt it was the same condition described by Terry, and by Payne and himself. Terry called the lesion retrolental fibroplasia and concluded it was an acquired manifestation. Reese and Payne designated the lesion as persistence and hyperplasia of the primary vitreous. Krause believes the lesion represents a faulty development of the neuroectoderm in that portion where it forms the retina as well as the brain. Reese further stated that he felt the incidence of mental retardation was no higher than in the series of cataract associated with rubella and did not believe that Krause's findings justified the assumption that mental retardation is a usual accompaniment of the ocular lesion. Future studies will probably clarify the picture.

COMMENTS

From the foregoing, it is apparent that there is a wide variety of congenital cataracts.

It is well known that certain types have a hereditary tendency. Franceschetti⁸³ has listed the following as types with an hereditary tendency: congenital total cataract, lamellar cataract, embryonal nucleal cataract, coralliform cataract, spear cataract, floriform cataract, anterior axial embryonal cataract, anterior and posterior polar cataract, axial fusiform cataract, stellate cataract, and disc-shaped cataract.

Intrauterine trauma may at times produce lens changes as seen in the reduplication cataract.

As Ida Mann has pointed out,⁸⁴ we know experimentally that toxic substances administered to the mother during pregnancy may cause lens changes. It is known that interference with calcium metabolism and parathyroid secretion will produce the same opacities as will avitaminosis.

Recent work that has been done on rubella cataract has shown that infection in the mother is capable of producing cataracts. The section through the eye of a seven-weeks embryo with a history of rubella in the mother during the fifth week of pregnancy would seem to bear out the contention that the damage is done at the time of the infection.

In addition to the changes in the lens substance itself, there may be abnormalities of the vascular capsule, which is mesodermal, and which may cause such changes as retrolental fibroplasia, persistence, and hyperplasia of the primary vitreous. This is often associated with changes in the lens itself.

In conclusion, as Ida Mann⁸² points out, it must be remembered that the lens is transparent in its normal development and, therefore, all congenital lens opacities are pure aberrations and not arrests.

THE TREATMENT OF LEWISITE AND OTHER ARSENICAL VESICANT LESIONS OF THE EYES OF RABBITS WITH BRITISH ANTI-LEWISITE (BAL)*

IDA MANN, A. PIRIE, AND B. D. PULLINGER
London, England

At the beginning of the war, in 1939, work on the mode of action of and possible antidotes for the vesicants likely to be used in chemical warfare was initiated by an extramural research team (supported by the Chemical Defence Research Department of the Ministry of Supply) in Oxford under the direction of Prof. R. A. Peters. Peters, Stocken, and Thompson (1945) have described the preparation of the new compound 2:3 dimercaptopropanol (BAL) and its action as an antidote to the arsenical vesicants, and the reader is referred to this paper for details. The present paper describes experiments undertaken by the authors to determine the effect of BAL on lesions produced by Lewisite and other arsenical vesicants on the eye of the rabbit. The work was begun in 1941 at the laboratories of the Imperial Cancer Research Fund and was completed at Oxford. It was supported throughout by the Chemical Defence Research Department of the Ministry of Supply.

The action of BAL in averting, aborting, or reversing the destructive effect of Lewisite burns of the eye is so striking and can be so well-observed in the rabbit that it is worthy of recording in detail. No similar therapeutic effect on a destructive lesion of the eye is known, and the pathologic principle involved is a new one. Arsenicals are known to combine with thiol compounds, and Voegtlin

(1923) suggested that the toxicity of arsenic lay in its ability to combine with the $-SH$ groups of compounds, such as glutathione, which are essential in cell metabolism. Stocken and Thompson (1941) analyzed the compound of Lewisite and keratein, a protein containing many thiol groups, and they found that each Lewisite molecule combined with two thiol groups. This led them to prepare the dithiol compound 2:3 dimercaptopropanol (BAL) as a soluble penetrating "chaser" for Lewisite in the tissues. BAL combines with Lewisite readily to form a relatively stable compound and, therefore, competes with tissue proteins and other $-SH$ containing compounds for any Lewisite present. It penetrates the eye tissues with great rapidity, and the resultant compound of BAL and Lewisite is relatively harmless and capable of excretion through the kidneys. BAL reacts with Lewisite on the cell surface or within the cell itself and a most striking reversal of an intracellular destructive pathologic process can be observed. The eye is particularly suitable for demonstrating this new type of therapeutic reaction because of the ease with which changes in the eye can be observed over a long period of time by the aid of slitlamp microscopy.

METHODS

Rabbits were used in all experiments. They were mainly of mixed Dutch stock, chosen for eye color. They were housed in individual cages and fed a mash of bran, toppings, and sugar-beet pulp, together with fresh greens each day. Care was taken to use young, healthy animals as it was necessary to watch their eyes

* From the laboratories of the Imperial Cancer Research Fund and the Nuffield Laboratory of Ophthalmology, Oxford. Acknowledgement is made to the Director General of Scientific Research (Defence), for permission to publish this paper.

over a long period. A total of 150 eyes was used.

The experiments may be divided into five essential groups:

1. Effect of BAL itself on the normal eye.

2. Effect of Lewisite alone on the normal eye.

3. Effect of BAL on eyes injured by Lewisite.

4. Effect of BAL on eyes injured by other arsenicals.

5. Effect of BAL on eyes injured by a mixture of Lewisite and dichlorodithiylsulphide (mustard gas).

RESULTS

1. EFFECT OF BAL ITSELF ON THE NORMAL EYE

The effects of solutions of BAL of various strengths can be expressed briefly in tabular form, as they vary roughly with the concentration (table 1).

TABLE 1
EFFECT OF BAL ITSELF ON THE NORMAL EYE

Strength of Solution (BAL in Thiodiglycol,	Method of Application	Time (After Application)	Changes Observed
1 percent	One drop in eye	5-15 min.	Very slight contraction of pupil; no other change
	Continuous eye bath for 15 min.	5-15 min.	Pupil contracted; conjunctiva congested; epithelium damaged; recovered in a few hours
5 percent	One drop in eye	5-15 min.	Slight contraction of pupil; no other change
	Continuous eye bath for 15 min.	5-15 min.	Contraction of pupil; damage to epithelium, ?to substantia propria; flushing of iris; complete recovery
10 percent	Continuous eye bath for 15 min.	1-24 hr.	Contraction of pupil; corneal haze; chemosis; iritis
		4 days	Deep corneal vascularization
		12 days	Retrogression of vessels
		15 days	BAL dots* visible
20 percent	Continuous eye bath for 15 min.	1-24 hr.	Severe reaction with corneal haze, chemosis, and iritis
		4 days	Vascularization
		4-30 days	Acutely inflamed
		3 months	Healed with irregular vascular scar
25 percent	Single drop in eye	Immediate	Surface corneal opacity and contracted pupil
		24 hr.	Slight iritis and corneal edema
		10 days	Eye clear
		15 days	BAL dots*
30 percent	Single drop in eye		Similar to 25% solution
Undiluted BAL	Single drop in eye		Similar to 25% solution but may leave slight permanent nebula

* BAL dots are described in detail on page 423.

BAL dots. The appearance referred to (Table 1) as "BAL dots" was first visible on the 15th day after treatment of the eye with 10- to 30-percent solutions of BAL. It consisted of a series of opaque white and glistening dots visible with the slit-lamp in the area of maximum previous disturbance of the substantia propria; namely, the center of the cornea. These dots were evenly distributed under the epithelium within the superficial third of the substantia propria, and were visible by internal illumination (sclerotic scatter), as well as by direct (broad and narrow beam), and by retro-illumination. They were about the size of a corneal corpuscle and were of various shapes, ring forms, horseshoes, and short rods alternating with round dots. Their nature was investigated by cutting frozen tangential sections of the cornea, staining with hematoxylin and examining with an oil-immersion lens. They were then seen to be deposits of a hyaline, amorphous material in various sized granules lying within the cytoplasm of invading macrophages. Their exact nature is unknown and, so far, they have only been seen after application of BAL. They are not of any clinical importance. They remain stationary for a long time, but may change their position owing to the migration of the macrophages carrying them. In one eye, they were observed for 10 months; in another, for 14¾ months. They usually begin to thin out and to occupy a larger area in two to three weeks after they are first observed. If they have been first observed in a central clump, they will, by four or five months, have migrated peripherally so that they form a widely dispersed ring not quite half way to the limbus. In some cases, they spread out and disappear entirely within a year, in others some traces remain for at least 15 months.

It is thus evident that continuous ap-

plication for 15 minutes (as an eye bath) of a large amount of BAL in strengths varying from 5 percent to 20 percent is harmful, but that a single drop of a 30-percent solution can be used with safety. In subsequent therapeutic experiments, 10-percent and 20-percent solutions were generally used. The exact strength within these limits appears to be immaterial, although there is a slight balance in favor of 20 percent. Both stronger and weaker solutions than these are also effective in the presence of Lewisite. The action of pure BAL on an uncontaminated eye was also investigated and found to be similar to that of a 30-percent solution, but unlike this, it leaves a very slight permanent nebula.

2. EFFECT OF LEWISITE ALONE ON THE NORMAL EYE

In order to judge the therapeutic action of any substance, it is necessary to be able to produce a standard lesion, the course of which, if untreated, can be predicted with certainty. Any alteration in this course can then with safety be put down to the effect of the treatment given. We, therefore, attempted to produce standard lesions with Lewisite vapor and with liquid Lewisite.

It was found impossible to produce standard lesions with Lewisite vapor with the means at our disposal, so that liquid Lewisite was adopted in practically every case. Contamination by a 0.1 to 0.2 mg. droplet of Lewisite was used, since this produced complete destruction of the eye in every case. The exact site of application of the droplet of Lewisite made no difference to the end result; namely, destruction of the eye. The course of events leading to this could, however, be slightly modified by different techniques of application.

Thus, if the droplet were placed on the center of the cornea of an anesthetized

rabbit and the eye was carefully held open so that the lids did not come in contact with the cornea for 15 minutes, the eye was lost by shrinking after a stage of vascularization of the cornea (central control lesion).

If, on the other hand, the rabbit was

splash-and-blink lesion simulated more nearly that expected in war.

The course of events following these two types of lesion can be summarized and used for comparison with the treated series* (tables 2 and 3).

It is thus obvious that Lewisite leads

TABLE 2
CENTRAL CORNEAL CONTROL LESION WITH 0.1 TO 0.2 MG. LIQUID LEWISITE

Time	Lids and Conjunctiva	Cornea	Iris
Immediate		Central opacity	
2-5 min.	Lacrimation		Pupil strongly contracted
20 min.	Severe edema of lids and conjunctiva		
3 hr.	Extreme chemosis and hemorrhages	Corneal epithelium shed. Edema of substantia propria all over	
24 hr.	Chemosis and lid swelling much better. Large conjunctival hemorrhages	Staining all over with fluorescein	Severe exudative iritis
3 days	Very little discharge	Corneal epithelium healing	Severe iritis
6-8 days	Very little discharge	Epithelium healed. Uniform marginal vascularization of cornea. Vessels reach center of cornea	
3 weeks	Slight mucopurulent discharge	Separation of central slough or central perforation	Depigmentation of iris
6 weeks	Eye shrinking	Proliferation of limbal pigment	Anterior synechiae. Pupil blocked with cyclitic membrane

allowed to blink immediately after the application, so that the Lewisite was spread over the cornea, conjunctiva, and lids, destruction was more rapid and complete, the cornea perforating before any vascularization had taken place. This type of lesion simulated that to be expected from a droplet of Lewisite spray entering the eye in warfare or in a factory accident, and was known as the splash-and-blink control lesion. Both this and the central control lesion were used in testing the efficacy of BAL, since the central lesion allowed of more detailed observation of the course of the antidotal action; while the

immediately to gross edema and ends in complete destruction of every cell with which it comes in contact. It penetrates the tissues rapidly and exerts an almost immediate effect on the intraocular tissues as well as on the surface cells.

3. EFFECT OF BAL ON EYES INJURED BY LEWISITE

Studies of the course of such standard

* For a detailed description of the clinical pathology of Lewisite lesions of varying severity see Mann, Pirie, and Pullinger, "A Study of Lewisite Lesions of the Eyes of Rabbits." This JOURNAL, October, 1946.

Lewisite lesions treated with BAL at varying times after contamination revealed that the destructive effect could, under certain conditions, be entirely prevented.

This is demonstrated in Figures 1 to 12. Figures 1 to 6 show the stages of destruction in an untreated splash-and-blink lesion. Figure 7 shows one untreated (con-

eye in which treatment was delayed for 10 minutes. In this case, the eye became normal, but in similar cases seen in Figures 11 and 12 some permanent depigmentation of the iris remained, although the eyes were functionally perfect. These photographs show that we are dealing with a very remarkable reversal of a destructive lesion. The clinical changes must

TABLE 3
SPLASH-AND-BLINK CONTROL LESION WITH LIQUID LEWISITE

Time	Lids and Conjunctiva	Cornea	Iris
Immediate	Lids tightly closed. Lacrimation	Opacity wherever Lewisite in contact	
2-5 min.	Edema of 3rd lid beginning		Pupil strongly contracted
20 min.	Extreme edema of lids and conjunctiva		
3 hr.	Very marked swelling. Hemorrhages and dilated lymphatics all over conjunctiva		
24 hr.	Slightly less swelling	Cornea hazy and grossly edematous	Severe iritis
3 days	Eye closed with severe discharge	Severe edema	Severe iritis
10 days	Purulent discharge. Lids brawny	Cornea opaque and liquefying. No attempt at vascularization or repair	Iris not visible
3 weeks	Lids and conjunctiva contracting on to globe	Descemetocoele on the point of rupture	
4 weeks	Almost complete symblepharon to disorganized globe	Phthisis bulbi	

trol) eye and one apparently normal eye. This apparently normal eye had received the same dose of Lewisite, plus one drop of 20-percent BAL in thiodiglycol applied immediately after the Lewisite. This shows in a very striking manner the complete protection afforded. Figure 8 shows an intermediate stage of cure of a similar eye; the cornea was still slightly edematous in two days, but normal in three. Figure 9 shows an equally good result obtained by waiting five minutes before applying the BAL. Figure 10 shows an

be dealt with in some detail as the pathologic reaction involved is unusual.

Treatment of central corneal lesions. These lesions were used in the first group of therapeutic experiments to determine the effect on the cornea, iris, and ciliary body of treatment with BAL at varying times after contamination. Twenty-percent BAL in thiodiglycol was used in most cases, but the results were very similar for any concentration from 5 percent to 30 percent. The time series was worked out entirely with the 20-percent

Fig. 2 (Mann *et al.*). Another eye (rabbit) two hours after contamination with liquid Lewisite. Note the swelling of the lids and the discharge. Chemotic conjunctiva overlaps the pupil at the inner canthus.

solution. The eyes were treated with BAL immediately, and at 1, 2, 3, 4, 5, 7, 9, 11, 13, 15, 20, 30, and 45 minutes after contamination.

The sequence of events in eyes treated immediately or 1, 2, 3 or 4 minutes after contamination was similar and as follows. (This should be compared with the sequence in the central control lesion in Table 2.) The site of application of the Lewisite became opaque immediately, and the pupil contracted strongly in two minutes, as in the control, showing that the Lewisite reached the iris and was not neutralized by the BAL entirely on the surface. After the BAL was dropped on, the central opacity became more gray and

diffuse, and the epithelium in the center shed off in about six minutes. At 10 minutes, slight chemosis began, and an occasional conjunctival hemorrhage was seen. This edema then rapidly subsided, never reaching extreme proportions. An hour after the application of BAL, it had disappeared, only a little conjunctival hyperemia remaining. The site of applica-

Fig. 4 (Mann *et al.*). Left eye of rabbit shown in Figure 3.

tion of the Lewisite was then localized, white, and involved the whole thickness of the cornea. The surrounding cornea was grayish. The pupil was beginning to dilate again. The eye looked irritated, the central part of the cornea was denuded, and the lesion showed as a very clear-cut opacity. The striking chemosis and swelling of the substantia propria seen in the control were absent.

Fig. 5 (Mann *et al.*). Similar untreated Lewisite lesion in another rabbit on the 12th day.

Fig. 6 (Mann *et al.*). End result of untreated Lewisite lesion. The eye has perforated, and the lids have contracted down on it. Only a small discharging palpebral aperture is visible. 30 days after contamination.

In 24 hours, there was slight mucopurulent discharge, but the eyes were open, and the animal seemed to have little or no discomfort. The central part of the

cornea stained with fluorescein and was hazy, but the limbus was normal. There was disturbance but not destruction of the

Fig. 8 (Mann *et al.*). Left eye of rabbit, seen in Figure 7, two days after Lewisite contamination and immediate treatment with 20-percent BAL. Note corneal edema and slight haze and roughening. There is no iritis. The eye became perfectly normal.

Fig. 9 (Mann *et al.*). Eye of a rabbit contaminated with Lewisite 26 days previously and treated after five minutes with BAL. The eye is normal.

endothelium in the central part. No trace of iritis or intraocular response of any kind was present.

In two days, the cornea was clearer, and only a small central area stained. This was healed by the fourth day, when the eye was open, bright, and normal, except for the small, central lesion which showed as a yellowish, slightly depressed area. It resembled an ulcer, but the epithelium was intact over it. On this day, the invasion by polymorphs and macrophages described by Pullinger and Mann (1943) as a stage in the process of avascular healing of the cornea could be observed with the slitlamp. It was greater by the seventh day, when the cells could be seen surrounding and invading the central localized opacity. The whole structure of the cornea in this region, including the collagen fibrils themselves, appeared to be altered and destroyed. The barrage of invading cells gradually extended into and beneath the lesion. Long, new, silky fibrils appeared, extending into it from the margins and gradually orientating themselves in the direction of the corneal lamellae, reconstituting them. This process took some time, slowly continuing

for about three weeks, during which time the eye was clear, bright, and practically normal, except for biomicroscopic changes in the central area.

By about the 25th day, the new tissue in the repaired area had pushed out a small, central, subepithelial bleb of corneal debris. This gradually seemed to liquefy until it appeared as a minute vesicle which then became absorbed without rupturing. It took almost three months to disappear to slitlamp examination but, clinically, the eye appeared normal throughout. This slow casting off and repairing of a small portion of the corneal substance was interesting to watch and seemed to indicate that, at the point of maximum concentration of the Lewisite, a minute area of irreversible destruction occurred, no matter how rapidly the BAL was applied. The end result was, however, always repair, although a very faint difference in texture of the central fibrils of the substantia propria could be detected with the slitlamp. In a few eyes, the area of repair remained slightly thinner than the rest of the cornea and appeared as a

Fig. 10 (Mann *et al.*). Eye of a rabbit contaminated with liquid Lewisite 20 days previously and treated after 10 minutes with BAL. The eye is normal.

minute facet, but this often became filled and flattened out by hyperplasia of the epithelium overlying it.

If the application of BAL was delayed for five minutes, the changes observed were more severe, and the process of repair took longer, although the end result was equally good. The immediate course of events was similar to that described for 1-, 2-, 3-, and 4-minute intervals, with the exception that the mucopurulent discharge continued for three days, and the eye appeared very tender to touch until the third day. On the fourth day, the epithelium was healed, and a pigment slide was present (Mann, 1944). Edema of the substantia propria extended to the limbus all round, and the limbal vessels were engorged. They began to invade the cornea on the fifth day, as in the untreated lesion. It appears likely that the signal for corneal vascularization is always extension of edema of the substantia propria to the limbus. No vessels were ever seen invading through normal substantia propria from a normal limbus.

Fig. 11 (Mann *et al.*). Eye of a rabbit contaminated with liquid Lewisite 18 days previously and treated after 10 minutes with BAL. The result is not quite so good as that seen in Figure 10. There is still slight corneal edema and a patch of depigmentation of the iris can be seen below.

Fig. 12 (Mann *et al.*). Eye of a rabbit contaminated with liquid Lewisite 26 days previously and treated after 10 minutes with BAL. The result is good, the cornea being clear, but there is an area of depigmentation of the iris in the lower part.

Instead of extending exuberantly to the center, as in the untreated control, these vessels began to retrogress and the edema to clear on the 12th day. It was then evident from the presence of faint opacities in the aqueous that there had been a mild iritis. No synechiae were formed and no depigmentation occurred. The vessels all disappeared rapidly, and the center of the lesion healed with the formation and absorption of the small bleb described above. The end result was as good as if the BAL had been applied immediately, but the course of the healing included early, but rapidly reversed, vascularization and a very mild iritis. Similar results were obtained after delays in application of BAL for 7, 9, 11, 13, and 15 minutes, the vascularization after each longer delay in treatment becoming more severe and taking longer to retrogress. In a few cases, "BAL dots" were seen, but these were rare when BAL was used after Lewisite.

If, however, BAL was not applied for 20 to 25 minutes after Lewisite, some of the changes were irreversible, and healing occurred with the formation of vascular corneal scars, produced by the entry of fibroblasts as well as the polymorphs and macrophages. The iritis also was more

severe, and areas of depigmentation were left on the iris. The course of events in such eyes treated after 15 or 25 minutes is summarized in Table 4.

It will be seen that, in the eye described in Table 4, the record is almost the same as for the untreated eye (table 2) for the first 24 hours. A difference from the con-

It will be seen that, if BAL is applied 15 or even 25 minutes after Lewisite, there is the possibility of retaining a functional eye, although the initial period of severe damage gets longer. The time at which reversal of the change can be definitely recognized is, with these long time intervals, about 12 days, during which time

TABLE 4
COURSE OF A CENTRAL CORNEAL LEWISITE LESION TREATED WITH BAL AFTER 15 MINUTES

Time	Lids and Conjunctiva	Cornea	Iris
(Application of Lewisite)			
Immediate		Central opacity	
2-5 min.	Lacrimation		Pupil strongly contracted
15 min. (Application of BAL)			
3 hr.	Severe edema of lids and conjunctiva but not so severe as control	Corneal epithelium shed. Edema of substantia propria all over	Faint aqueous flare
24 hr.	Chemosis and lid swelling better. Subconjunctival hemorrhages	Staining nearly all over with fluorescein	Aqueous flare only
3 days	Practically no discharge	Epithelium healing	Aqueous flare only
6 days	Practically no discharge	Epithelium healed. Marginal vascularization of cornea	
7-12 days	No swelling or discharge	Central opacity. Margin clearing and vessels retrogressing	Depigmentation of part of iris. Aqueous clear
3 weeks	Normal	Small central nebula and bleb only. Vessels all empty and barely detectable	No iritis

trol is shown by the fact that only a mild iritis occurred at 24 hours and that the marginal vascularization, which began as in the control, retrogressed between the 7th and 12th days and finally disappeared. The treated eye at three weeks was normal, except for slight depigmentation of the iris; whereas, the control eye was vascularized to the center of the cornea and about to perforate.

the treated eye appears almost as severely damaged as the control.

If treatment is delayed for 30 minutes, the vascularization is more severe and the resulting scar larger. However, even after this long delay, the ciliary body and the rest of the eye are not seriously involved.

If treatment is delayed for 45 minutes, the course is exactly similar to that of an

untreated eye. The eye shrinks, the lens becomes opaque, the iris and ciliary body are disorganized, and the fundus partially depigmented. Treatment must, therefore, be given in the first half-hour and preferably in the first five minutes.

Treatment of splash-and-blink lesions. A somewhat similar series of results was obtained when the Lewisite was applied by the splash-and-blink technique. Since this method produces a much more severe lesion than does the central application,

minor changes could be detected.

If, however, the time interval was lengthened, the results were not quite so good as in the series of central lesions. This was probably due to damage to the limbus, which by producing local edema permits vascularization. The results are shown in Table 6.

The demonstration afforded by the foregoing experiments of the value of BAL led naturally to an investigation of alternative ways of using it. Experiment-

TABLE 5

COURSE OF CENTRAL CORNEAL LEWISITE LESION TREATED WITH BAL AFTER 25 MINUTES

Time	Lids and Conjunctiva	Cornea	Iris
(Application of Lewisite) (Application of BAL after 25 min.)			
Immediate to 13 days	Almost as control	Vascularized all round on 4th day like control	Severe, but not so severe as control
18 days	Very little discharge	Margin of cornea clearing and vessels less exuberant	Iris depigmented
27 days	Very little discharge	Most vessels gone but a few large ones enter dense central opacity	
6 weeks	No discharge	Central vascular scar with some degenerative change. Eye not blind	Permanent depigmentation

the course of healing was not expected to be so striking. It was, however, found that immediate application of BAL to such a lesion produced an even better result than with a central corneal lesion. This is explained by the fact that the Lewisite is instantly spread all over the eye by the lids and, therefore, does not penetrate anywhere so deeply before the BAL can reach it. There was no central area of destruction to be cast off and repaired. A small area of superficial destruction of the substantia propria was present, but this was quickly repaired. Clinically, the eye looked normal in two days and even with the slitlamp only

ally, it is easy to separate a rabbit's eyelids and insert a drop of BAL. Under war conditions, however, a man might have difficulty in overcoming the intense lid spasm produced by Lewisite either in administering first aid to another person, or in attempting to treat himself.

The question of method, therefore, seemed important and, as described, experiments were done using drops of 2-percent, 10-percent, 20-percent, and 30-percent BAL in thiodiglycol. The results for 10 percent and 20 percent were the same. It was then decided to try the effect of merely rubbing the solution on to the outside of the lids, without forcing

the eye open. The rabbit's lids were shaved, and the liquid was massaged into them with a glass rod. It was found that, if the liquid was applied to the skin of the lids, carefully avoiding the lid margin, no protection was afforded at all, and the eye lesion ran its destructive course. If, however, the liquid came in contact with the lid margin, a sufficient quantity seeped into the eye to act on the Lewisite rapidly and to avert destruction of the eye. It also relaxed the lid spasm and made it easy to insert more BAL into

plied to the lid margin up to 10 minutes after contamination, the results were excellent and were good after 15 minutes' delay. This strength was, therefore, used.

Since a solution of BAL might be difficult to carry about and to manipulate, experiments were tried incorporating the BAL in various ointment bases which were known to be nonirritating to a normal eye. It was found that the results of massaging 20-percent BAL ointment into the margins of the closed lids gave, on the whole, good results, although, in a

TABLE 6
APPLICATION OF BAL TO A SPLASH-AND-BLINK LEWISITE* LESION

Time	Result
Application of BAL	
Immediate	Very good indeed
5 minute-interval	Very good, but vascularization of cornea and slight depigmentation of iris
10 minute interval	Good result with clear cornea and depigmented iris
15 minute interval	Good result with lightly vascularized peripheral scar slow in healing
20 to 25 minute interval	Result more problematic. Some healed with vascular scars after iritis; some eyes were useless

* If slightly less than the destructive dose of Lewisite was used, the results were excellent up to 25 minutes.

the eye. Massage of BAL on to the lid margin, therefore, seemed the method of choice for man.

It was found that, if a 10-percent solution was massaged in, the amount of BAL which actually entered the eye was not always sufficient to reverse the Lewisite action. Application of BAL up to five minutes after contamination of the eye with Lewisite gave excellent results, but application between five and ten minutes after contamination with Lewisite was not so successful. Two out of 10 eyes perforated and were lost, and the rest healed with vascular scars, a worse result than would have been obtained if 10-percent BAL had been dropped into the eye.

If, however, 20-percent BAL was ap-

plied to the lid margin up to 10 minutes after contamination, the results were excellent and were good after 15 minutes' delay. This strength was, therefore, used.

Twenty experiments were done giving the results found in Table 7. It is obvious that good results can be obtained by massaging BAL ointment into the margins of the closed lids, but these results are not so good as those given by opening the eye and dropping a 20-percent solution directly on to the cornea. If this is done, no eye is completely destroyed until the time interval is more than 30 minutes.

4. EFFECT OF BAL ON EYES INJURED BY OTHER ARSENICALS

BAL was used in a short series of experiments as an antidote to methyl- and ethyldichlorarsine. The effect of methyl-

and ethyldichlorarsine on the eye is similar to that of Lewisite, itself, given in a comparable dose. The eye is rendered useless both when the liquids are applied to the center of the cornea, or by the splash-and-blink method.

The effect is not quite so violent as that of Lewisite. Only one out of five control eyes ended in perforation of the cornea; the others were blinded by shrinking of the whole eyeball or by the formation of dense vascular scars and gross destructive lesions of the intra-

On the whole, the results were slightly better than in the Lewisite series.

5. EFFECT OF BAL ON EYES INJURED BY A MIXTURE OF LEWISITE AND DICHLORODIETHYL SULPHIDE (MUSTARD GAS)

It had been suggested that use in war of a mixture of equal parts of Lewisite and mustard gas was a possibility. From an offensive point of view, it was difficult to see what would have been gained by mixing a rapidly destructive and almost instantly detectable chemical-war-

TABLE 7
RESULTS OF MASSAGING BAL OINTMENT INTO MARGINS OF CLOSED LIDS

10 min.	8	3	2	3

ocular structures. No difference in action could be detected between the methyl and ethyl compounds.

Treatment was carried out by dropping a 20-percent solution of BAL in thiodiglycol into the eye immediately and after intervals of 5, 10, 15, 20, and 25 minutes. Twelve eyes were used (two contaminated with methyl- and 10 with ethyldichlorarsine). In all but three, the application was by the splash-and-blink technique. The results obtained were similar to those obtained with Lewisite, with the exception that "BAL dots" were more readily detected in the healed eyes than they were in the Lewisite series. Immediate application saved the eye completely. Application of BAL up to 25 minutes after contamination also saved the eye in every case. In several eyes, however, small vascular scars and patches of depigmentation of the iris remained.

fare agent with one whose chief advantages were slowness of action and absence of immediate warning effects. It was, however, decided to investigate the action of BAL against such a mixture in the eye. We know already that BAL exercises no curative action on the lesion caused by mustard gas alone. It does not make it worse, and any action it may have is a purely mechanical one and not specific in any way.

We did not know either the effect on the eye of mixing Lewisite and liquid mustard gas, nor whether BAL would exercise any effect on the mixture. Eight experiments only were done. The results were very clear cut and in accordance with what we know of the action of Lewisite and of mustard gas on the eye and of the effect of BAL. They can be briefly described.

If a 50:50 mixture of Lewisite and

mustard gas is applied to a rabbit's eye in the manner described for Lewisite (central corneal lesion and splash-and-blink lesion), the course of events is exactly that which would have been expected from Lewisite alone. The eye is destroyed in the same time and by the same process. Since in the case of lesions with mustard gas alone, we knew that the course of a central corneal lesion is not the same as that of one involving the limbus (Mann and Pullinger 1940, 1942, 1942, and Mann 1942), we also tried the effect of an untreated limbal lesion made with the mustard-gas-Lewisite mixture. Its course was again that of a pure Lewisite lesion.

We, therefore, tried the effect of immediate treatment with 20-percent BAL of a central-corneal lesion produced with 50:50 Lewisite-mustard gas. The eye recovered without iritis or vascularization and also without extrusion of corneal debris. The result was better than if Lewisite alone had been used. This is explicable by the fact that, in a standard droplet of the mixture, there was less Lewisite than was used in the first group of experiments described above (in which a very small portion of the corneal substance was destroyed before the BAL could act). The central nebula resembled the "silky" result of a central, non-vascularizing mustard-gas lesion and disappeared entirely.

If the same dose of the mixture was applied as a droplet astride the limbus and treated immediately with BAL, the result was very interesting. The prophylactic effect on the Lewisite moiety was complete. No Lewisite iritis, vascularization, or separation of debris occurred. Healing, however, was delayed as the lesion ran the typical course of a small, untreated limbal mustard-gas lesion. On the fourth day, a secondary edema involved most of the cornea and

small blood vessels, preceded by intra-corneal hemorrhages and showing pointed ends, invaded the limbus on either side of the lesion and elsewhere where the edema reached the limbus. These vessels were deep and of a shape and arrangement known to be typical of vascularization following mustard-gas burns. They remained mildly active for about eight weeks, and the eye finally healed with only a few traces of empty vessels. This shows a very neat "sorting out" and neutralization of the Lewisite molecules by the BAL; the mustard-gas action being unaffected.

Treatment by Bal was also given to splash-and-blink lesions with the Lewisite-mustard-gas mixture. The immediate application prevented all Lewisite effect, but slight edema from the mustard gas was visible at the lower limbus, and a few deep vessels invaded here on the sixth day. These disappeared in four weeks.

If treatment of such a splash-and-blink lesion was delayed for 15 minutes (or even 5 minutes), a good deal of vascularization occurred. The vessels were numerous and arranged in straight rows like those typical of Lewisite, but they were larger than these usually are and accompanied by a few intracorneal hemorrhages which we have come to look on as very suggestive of mustard-gas burns. The eyes cleared in about six weeks, leaving faint, vascular nebulae. There appeared to be a mixed effect here, the Lewisite change having begun before the BAL could act.

It is obvious that BAL should be used in treatment of a mixed contamination and as speedily as possible.

SUMMARY AND CONCLUSIONS

1. The action of 2:3 dimercaptopropanol (BAL) was studied on the intact rabbit's eye, on eyes contaminated with droplets of Lewisite, methyl- and ethyl

dichlorarsine and with a mixture of Lewisite and liquid mustard gas.

2. A single application of BAL in solutions of 1 percent to 30 percent in thiodiglycol to the intact rabbit's eye was without permanent ill effects. Application of pure BAL was slightly more irritating but the eyes recovered from this also. BAL was, therefore, a possible therapeutic substance for eye lesions.

3. Application of BAL within five minutes to an eye contaminated with a destructive dose of Lewisite was successful in preventing the action of the Lewisite. Applications delayed for varying times up to 25 minutes also saved the function of the eye, although partial permanent damage remained.

4. A 20-percent solution of BAL in thiodiglycol gave the best results when dropped into the eye. Surprisingly good results were, however, obtained with 20-percent ointments rubbed onto the closed lids along the line of the palpebral aperture.

5. BAL is equally effective as an antidote to methyl- and ethyldichlorarsine.

6. BAL is effective against the Lewisite moiety of a Lewisite: mustard-gas mixture, but the lesion due to the mustard-gas portion progresses uninfluenced.

TESTS FOR HETEROPHORIA*

RELIABILITY OF TESTS, COMPARISONS BETWEEN TESTS, AND EFFECT OF CHANGING TESTING CONDITIONS

RICHARD G. SCOBEE, M.D.

St. Louis, Missouri

AND

EARL L. GREEN, PH.D.

Columbus, Ohio

Muscle balance is a subject in which the student of ocular functions almost invariably takes an early interest. The discovery of several points soon lessens this interest. Among these is the clinical observation that relatively large amounts of heterophoria may be present in an individual and yet that individual may be perfectly comfortable. Another of these is the statement found in the literature on ocular muscle balance that heterophoria varies not only from day to day but also from moment to moment in the same individual.^{1,2} These two observations lead many students to the conclusion that it matters little what test of heterophoria is used or how carefully it is performed since the results will probably be inaccurate and of dubious significance.

Nevertheless, in any thorough survey of ocular functions, heterophoria cannot be neglected. Heterophoria is a deviation of the eyes from the position of fixation when fusion is prevented.² Measurements of heterophoria, therefore, reveal how much of a motor task fusion has to perform in bringing images upon corresponding retinal points. Certainly the individual with little or no heterophoria, all other

things being equal, will secure binocular single vision with much less effort than the individual with marked heterophoria. The average clinician is not particularly concerned with whether his patient has 4 prism diopters of exophoria or 6 prism diopters of exophoria, unless that exophoria is indicative of symptom-producing strain. Neither is he particularly concerned when a patient tested on one day shows 4 prism diopters of exophoria and when tested again, on a subsequent visit, shows 6 prism diopters of exophoria.

When it becomes necessary, however, to select large numbers of men in accordance with certain arbitrary standards of heterophoria, as in the selection of pilots for the Army Air Forces, the amount of the heterophoria and the reproducibility of the determinations become important. To illustrate the point, the exophoria limit for pilots for Class 1 in the Army Air Forces has been chosen as 5 prism diopters. An applicant for pilot training who has more than this amount will receive no further consideration. If, after attaining his coveted "wings," a pilot is found to manifest more than the limit of 5 prism diopters of exophoria at any time, he will be "grounded," perhaps for a time, perhaps permanently.

At least three sources of error may be recognized in the routine performance of tests now available. First, an individual may have inconstant amounts of manifest heterophoria.³ This variation may be due either to a variation in the amount of

*From the Departments of Ophthalmology and Statistics of the Army Air Forces School of Aviation Medicine, Randolph Field, Texas. The authors are deeply indebted to Herbert L. Moss for assistance in testing for heterophoria, and to Walter I. Shimer and Lester G. Mertz for assistance with the statistical analysis. Read before the American Academy of Ophthalmology and Otolaryngology, October 14, 1946, Chicago, Illinois.

manifest heterophoria of the subject or to inaccuracies in the testing technique. The two sources of variation are inseparable and may be considered together as individual variation.) In evaluating tests for heterophoria, those which show little individual variation in comparison with the total range in the sample of tested subjects will be preferred over those which show large individual variation. This is the same as saying that the test must have high reproducibility or *reliability*.

Second, examiners may not all perform the test for heterophoria in exactly the same way. Particularly if a large number of individuals must be examined at many different places in short periods of time, as in time of war, the multitude of examiners will not have equal degrees of competence in the administration of the test.

Third, different tests or conditions of testing may not be equally effective in converting similar amounts of the total heterophoria into manifest heterophoria which can be measured.) Despite the number of tests available, a comparison of the tests by modern statistical methods has seldom been made. Cridland's work⁴ stands almost alone in this field.

The present study is directed toward answering some of the questions about the available tests for heterophoria. First, we shall estimate the reliability of the screen Maddox-rod test, and in the same experiment look for systematic differences between examiners which may contribute to unreliability.) The screen Maddox-rod test was chosen because this test, described by Dolman,² has been in use throughout the Army Air Forces. Second, we shall make comparisons between several available tests, including among these the screen and parallax test which is universally regarded as being the most accurate one.) These comparisons were made

at two different testing distances, 20 feet for distance fixation and 13 inches for near fixation. Third, we shall attempt to estimate the effect of varying the testing conditions upon the Maddox-rod test. The alternative conditions studied were a light vs. a dark room, the use of screening vs. not screening, the placing of the Maddox rod over the dominant vs. the nondominant eye, and the use of a red vs. a white Maddox rod.

DESCRIPTION OF TESTS

All of the tests used in this study are familiar to students of ocular muscle balance. With one exception, only brief descriptions will be given.

Screen and parallax test. A 1-cm. light was used at 20 feet and an ophthalmoscope with the head removed was used at 13 inches. A cover was shifted from one eye to the other, square prisms being changed behind the cover until any objective movement of the eye and any subjective movement of the light had ceased.

von Graefe's prism diplopia test. At a distance of 20 feet, a 20/100 size Snellen letter "E" was employed as a test object, while at 13 inches a similar letter "E" 2 mm. in height was used. The test object was adequately illuminated at both distances and an insuperable diplopia was created with a vertically placed 5-diopter prism before one eye. The examinee was asked to adjust the two images (by means of a Risley rotary prism) so that they were in the same vertical line.

Screen Maddox-rod test. Because the study to be reported concerns the technique of the screen Maddox-rod test, the test is described in full. At 20 feet, the test object was a muscle light, 1 cm. in diameter; at 13 inches, it was an ophthalmoscope with the head removed. All lights in the immediate vicinity of the muscle light were turned out but the room was not entirely darkened. With the Maddox

rod placed before the nondominant eye, a cover was also held before the same eye and removed regularly for a period of 1 second at about 3-second intervals, meanwhile allowing the dominant eye to maintain fixation constantly. This very brief uncovering or "flashing" of the nondominant eye had for its purpose a further weakening of the fusion control. For the measurement of heterophoria, a Risley rotary prism is rotated into position (also before the nondominant eye) and set between 3 and 4 diopters "off" of the zero position; this forces the examinee to make some adjustment even though orthophoria is present. The examinee grasps the handle of the rotary prism and, while the muscle light is being "flashed" before the eye behind the Maddox rod, he is instructed to adjust the line so that it bisects the light.

Maddox-rod test. This test is the same as the screen Maddox-rod test just described except that screening is omitted.

Maddox-wing test. Used at 13 inches, this is a well-known test and needs no particular elaboration other than to mention that an arrow is seen by the right eye only, while calibrated lateral and vertical scales are seen by the left eye only.

+ *Thorington test.* This is also a well-known test and employs a Maddox rod. Linear scales, calibrated in units of 2 prism diopters, are drawn on the face of a card which is mounted on the head of a flashlight, a pin hole being located at the exact center of the card which is also the point of intersection of the lateral and vertical scales. The flashlight bulb is visible only through the hole in the card's center. The testing distance is 13 inches. A Maddox rod is placed before one of the examinee's eyes and he is asked to state at what point the line of light (as seen through the Maddox rod) intersects the calibrated scales.

RELIABILITY OF THE SCREEN

MADDOX-ROD TEST

The problem of reliability of the screen Maddox-rod test was approached from the point of view that if the test were not reproducible under relatively ideal conditions, then it was not likely to be reproducible under the routine testing conditions necessary for the physical examination for flying used in the Army Air Forces. The experiment was therefore planned to yield a maximum reliability of the screen Maddox-rod test.

Plan of study. Two examiners, who had watched each other work and whose testing techniques were as nearly identical as possible, performed the tests. Both examiners tested each subject on each of two different days. No subject remained seated in the examination room for consecutive tests by both examiners; instead, one examiner examined the entire group of subjects for the day before turning them over to the second examiner. The test-retest interval varied from 1 to 5 days. Both lateral and vertical heterophoria measurements were made at each testing period. All subjects were tested at the 20-foot distance; none wore glasses and there was no correction of refractive error. The screen Maddox-rod test technique as outlined in the previous section was utilized throughout.

Limitations of the study. All subjects were aviation cadets who, theoretically, had a visual acuity of at least 20/20 in each eye, a normal amount of accommodation and convergence, and heterophoria of not more than 1 prism diopter of hyperphoria, 10 prism diopters of esophoria, or 5 prism diopters of exophoria. The population available for study therefore represented a special selection from the general population with the consequence that the heterophoria readings extend over a limited portion of the entire range.

Another limitation arose from the fre-

quency distribution of heterophoria which was not normal in form. A distribution for 131 subjects tails out to the right (the statistic of skewness, $g_1 = 1.38$, is 6.5 times its own standard error; the statistic of kurtosis, $g_2 = 4.37$, is 10.4 times its own standard error). To test the normality of distributions still further, data were borrowed from Cridland⁴ for the purpose. In one of these (the red-green test) there is significant skewness to the right and in the other (the Maddox-rod test) there is

limits of experimental error for all subjects. (The interaction $S \times E$ is not significant.) Similar statements may be made with respect to the records of vertical heterophoria. Under the relatively ideal conditions of this study, therefore, it was found possible to achieve a high agreement between examiners, and the results are similar to those which may be expected if a single examiner performed all the testing.

The measurements of both lateral and

Note: For lateral heterophoria, + means esophoria, - means exophoria; for vertical heterophoria, + means right hyperphoria, - means left hyperphoria.

significant skewness to the left. The inconsistency of these findings suggests no general way of transforming the heterophoria scale to normality at this time.

Results. The results of testing 50 subjects for lateral heterophoria and 49 subjects for vertical heterophoria are summarized in Table 1. Examiner A recorded an average of 1.10 prism diopters of esophoria and Examiner B, an average of 1.30. This difference is not significant ($F = 3.92$ where $F_{01} = 6.90$) and consequently there is no evidence of general disagreement between examiners. Furthermore the examiners agreed within the

vertical heterophoria are highly reliable when made with the screen Maddox-rod test. The coefficients of reliability are +0.95 and +0.92 for the two types of measurements, respectively. These coefficients are based upon the internal consistency of the four records taken on each subject and are computed by a method suggested by Hoyt.⁶ In practical terms, these coefficients mean that any careful examiner can make heterophoria measurements with sufficient accuracy to discriminate between subjects. A notion of the absolute accuracy with which heterophoria may be measured may be obtained

from the standard errors of single determinations. For lateral heterophoria, the standard error is 0.73 which means, approximately, that a lateral heterophoria measurement may be in error by as much as 1.5 prism diopters (2×0.73). For vertical heterophoria, the error may be as much as 0.4 prism diopters (2×0.18).

COMPARISONS BETWEEN TESTS

Many factors, both anatomic and innervational, determine the amount of heterophoria elicited by any one test at

test for use in testing large numbers of men, as in time of war, it is necessary to have an accurate test that can be administered in a minimum of time. Of all heterophoria tests, the screen and parallax test eliminates a greater number of innervational factors than any other test and thus allows the closest possible approach to the position of absolute rest. The screen and parallax test is considered somewhat tedious by the novice, however, and requires a fair degree of skill for proper performance. Hence it appears de-

TABLE 2

any one time. If it were possible to eliminate entirely all these innervational factors, then the eyes would assume the position variously referred to as the position of rest, the fusion-free position, or the fusion-frustrated position. Bielschowsky¹ has pointed out that any determination of the absolute position of rest is practically impossible because the totality of nervous influences cannot be eliminated in any way.

Various tests of heterophoria yield varying results in the same individual because varying numbers of innervational factors are eliminated by each of the different tests. In choosing a heterophoria

sirable to know how other tests of heterophoria compare with the screen and parallax test.

Plan of Study. Fifty aviation cadets were tested by a single examiner for lateral heterophoria on eight tests, three with a testing distance of 20 feet, and five with a testing distance of 13 inches. At 20 feet, the screen and parallax test, von Graefe's prism diplopia test, and the screen Maddox-rod test were used. At 13 inches, the screen and parallax test, von Graefe's prism diplopia test, the Maddox-wing test, the Thorington test, and the screen Maddox-rod test were used.

Results. It is obvious from the sum-

mary of results in Table 2 that the tests which use a testing distance of 20 feet do not agree precisely with each other. Yet the level of agreement is reasonably high considering the diverse nature of the tests. All three tests yielded about the same average heterophoria and about the same spread around the averages. The coefficients of correlation are equal within the limits of random sampling. There is no clear choice among these three tests based upon statistical evidence alone. From the standpoint of ease of performance and time required, the screen Maddox-rod test may be preferred by some to either von Graefe's prism diplopia test or the screen and parallax test.

When the heterophoria tests which use a testing distance of 13 inches are considered, the screen Maddox-rod test is apparently no longer the satisfactory test that it was at 20 feet (table 2).

The screen and parallax test, as expected, uncovered the highest average exophoria, 8.2 prism diopters. The screen Maddox-rod test uncovered an average of 5.9 prism diopters of exophoria. The other three tests were about equivalent. They uncovered an average of 3.0 prism diopters of exophoria in the sample of 50 subjects. The variabilities about the averages, as judged by the standard deviations, are quite different. Consequently, on the basis of the means and standard deviations alone, the five tests at 13 inches cannot be regarded as equivalent. The coefficients of correlation reveal that four of the tests would rank the subjects in approximately the same order of degree of heterophoria. The exception is the screen Maddox-rod test which is not sufficiently correlated with the other four tests to be used as a replacement for any one of those tests. The coefficient of correlation of the Thorington test with the screen and parallax test is 0.77, while that of von Graefe's prism diplopia test is 0.72, and that of the

Maddox-wing test is 0.68. The screen Maddox-rod test trails all the others with a correlation coefficient of only 0.48.

Although the screen Maddox-rod test is apparently in a class by itself at a testing distance of 13 inches, this may in part be due to the fact that the sample is preselected on the basis of the screen Maddox-rod test. Removal of this restriction might yield a higher correlation with the screen and parallax test. However, in another sample of similar subjects tested in similar fashion, the screen Maddox-rod test agreed well with the screen and parallax test. This sample is discussed in a later section.

It must be realized that the screen Maddox-rod test at 13 inches, although apparently in a class by itself, may possibly be the best instead of the worst test of heterophoria and that it may be measuring something that the other tests are not. It is unfortunate that the present state of our knowledge is insufficient to allow a decision to be made.

CONDITIONS OF THE MADDOX-ROD TEST

The screen Maddox-rod test has been found to have a satisfactory self-consistency, at least under ideal conditions, and a satisfactory agreement with the screen and parallax test when the testing distance is 20 feet. These facts, plus its relative ease of administration, make it a desirable test for use for routine measurements of heterophoria on large numbers of subjects, as in time of war.

The screen Maddox-rod test was chosen as the standard test for the Physical Examination for Flying (WD AGO FORM No. 64). Certain variations in the testing conditions appeared during the war, and their effect upon the heterophoria measurements was not known, at least not in quantitative terms. Among the departures from uniform conditions, the following alternatives were regarded as important

enough to merit special study: a light vs. a dark room, the use of screening vs. not screening, the placing of the rod over the dominant vs. the nondominant eye, and the use of a red vs. a white Maddox rod.

The effect of illumination in the testing room was investigated in a separate experiment. The other three alternatives were incorporated into a single experiment.

EFFECT OF ILLUMINATION

There are conflicting arguments in the literature on heterophoria about the

tions requiring visual efficiency which might reasonably be affected by heterophoria.⁴

METHODS

In an experiment designed to resolve this difference of opinion, lateral and vertical heterophoria was determined under two alternative conditions at a testing distance of 20 feet upon 60 subjects. All the subjects were aviation cadets and thus were a selected group. The two conditions of testing were:

1. *Dark.* The testing room was in com-

$n=60$ subjects.

* For the mean difference to be significant, t should exceed 2.66.

For lateral heterophoria, + means esophoria, - means exophoria; for vertical heterophoria, + means right hyperphoria, - means left hyperphoria.

amount of illumination required or permitted in the testing room. Those who prefer testing in darkness contend that, if only a spot of light is visible in an otherwise dark room, any planes of reference which would serve to fix accommodation will be lost in the darkness and therefore eliminated as variables. More heterophoria would be uncovered in this manner and hence the test made more accurate. The assumption behind this argument is, of course, that the test uncovering the most heterophoria is the best.

In contrast, those who prefer testing in an illuminated room maintain that the subject in darkness is in an abnormal situation in no way comparable to condi-

plete darkness except for a muscle light 1 cm. in diameter located 20 feet from the subject. The walls and ceiling of the room were painted black.

2. *Light.* The same room was used except that a 60-watt, frosted Mazda bulb was burning directly above the subject's head. Illumination measured 5 foot-candles at head-height directly beneath the bulb (9-foot ceiling) and 0.5 foot-candles at the end of the room (20 feet away) where the muscle light was located. In this illumination, all objects in the room could be seen fairly distinctly.

There was no appreciable lapse of time between tests, the light-room and dark-room determinations being made at the

same examination on each subject, although the order of the two tests was reversed in every other subject.

RESULTS

The results of the tests for heterophoria using the screen Maddox-rod test under the two conditions of illumination are summarized in Table 3. For this group of 60 subjects, the following assertions may be made:

1. *The average heterophorias, determined in light and in dark, are not sig-*

this experiment to support the claim that amounts of illumination up to that used in this study will significantly affect the measurement of heterophoria. Cridland⁴ reached a similar conclusion using the Maddox-rod test (without screening).

EFFECT OF SCREENING, EYE DOMINANCE, AND ROD COLOR

METHODS

One hundred subjects, all aviation cadets, were tested for heterophoria for

TABLE 4

n = 100 subjects.

+ means esophoria.

- means exophoria.

nificantly different. This is true for both lateral and vertical heterophoria.

2. *The variability* about the average, measured in terms of the standard deviation, is essentially the same for the two conditions of illumination, for both lateral and vertical heterophoria.

3. *There is a high correlation* between the determinations of heterophoria in light and in dark for both lateral and vertical heterophoria.

There is no evidence, therefore, from

near and distance fixation in a refracting alley 20 feet in length whose walls were painted black. The room was illuminated as described in the previous section on Maddox-rod determinations in a "light" room. The muscle light used at the 20-foot distance was a spot of light 1 cm. in diameter. At the 13-inch distance, the light was an ophthalmoscope with the head removed. Each subject was seated comfortably in a chair and determination of the dominant eye made by asking the

subject to sight the muscle light across the room through a 1-cm. hole in a 10- by 10-inch board which was held at arms' length with both hands, both eyes being held open. Heterophoria measurements were first made by the method of screen and parallax using the testing distances of 20 feet and 13 inches and employing a Beren's, plastic prism bar. The calibrations on the bar had been checked and found to be correct at a previous time.

whereas, the average at 13 inches was about 5.0 prism diopters of exophoria (table 4). The variation about the averages of the determinations at 20 feet is quite unlike that of the determinations at 13 inches (table 5). These facts make it necessary to preserve a separation of the data collected at the two different distances, and to look for the effects of screening, the dominance of the eye, and the colors of the rod separately in the two

TABLE 5

STANDARD DEVIATIONS OF HETEROPHORIA DISTRIBUTIONS AT 20 FEET AND AT 13 INCHES

	20 Feet		13 Inches

Red rod	2.98	3.07	5.66	6.07
	(7)	(8)	(7)	(8)
White rod	2.90	2.38	5.75	5.78

$n = 100$ subjects.

Test for homogeneity of variances:

$X^2 = 12.15$

$X^2 = 2.79$

$P = 0.10 - 0.05$

$P = 0.95 - 0.90$

After this measurement, a phorometer was accurately adjusted before the subject and testing was begun with the Maddox rod. Both red and white Maddox rods were used in testing before each eye separately, with and without the use of screening. This was done at testing distances of both 20 feet and 13 inches. All possible combinations of the four variables just mentioned were tested on each subject. This necessitated 16 separate measurements on each subject, the measurements being taken in random order.

The heterophorias determined at 20 feet are different from the heterophorias determined at 13 inches in several respects. In the present series of determinations upon 100 subjects, the average at 20 feet was about 1.5 prism diopters of esophoria;

bodies of data. Further, the variabilities in the eight distributions of heterophoria for the eight experimental conditions with a testing distance of 20 feet were found to be homogeneous when tested by the method of Bartlett.⁷ It appears, therefore, that whatever change is introduced into the heterophoria determination at 20 feet by a change in the experimental conditions, the change affects the average only and does not affect the distribution about the average. A similar assertion may be made for the changes introduced in the 13-inch test.

Screening vs. not screening at 20 feet.

When a Maddox rod is used in heterophoria determinations, it is placed before one of the examinee's eyes. The eye behind the rod perceives a spot of light as a

line of light while the other eye sees the spot as it really is. This distortion of dissimilarity of images disrupts fusion to a certain extent, thus allowing the eye behind the rod to deviate toward its dissociated position. The extent of this deviation may be measured exactly by the utilization of prisms. Dissimilarity between the two images of the same object as perceived by the two eyes does *not* completely abolish the fusion impulse.^{1, 8}

The cover test, that is, alternate occlusion of each eye separately, breaks up fusion as completely as is possible without actually occluding both eyes simultaneously. The covering or screening principle is the basis of the screen and parallax test.

The addition of intermittent screening of the eye behind the Maddox rod in testing heterophoria allows this test to approximate more closely the screen and parallax test, since the same basic principle is common to both. Omission of screening from the screen Maddox-rod test would seem to alter the test.

When the screen was used at 20 feet, the average heterophoria was found to be 1.74 prism diopters of esophoria; when the screen was not used, the average was 1.37 prism diopters of esophoria. The difference of 0.37 prism diopters is statistically significant, and indicates that on the average the use of the screen adds about 0.3 or 0.4 prism diopters to the heterophoria reading.

This difference due to screening appears to exist regardless of the color of the Maddox rod or of the dominance of the eye. When a red rod was used, the average was 1.85 prism diopters of esophoria with screening and 1.52 prism diopters of esophoria without screening, giving a difference of 0.33 prism diopters. When a white rod was used, the averages were 1.64 and 1.22 prism diopters of esophoria with and without screening, respectively,

giving a difference of 0.42 prism diopters. With the rod before the dominant eye, the difference was 0.39 prism diopters (1.69 with screening minus 1.30 without screening), and before the nondominant eye, the difference was 0.36 prism diopters (1.80 minus 1.44). Table 4 contains a summary of the means for all combinations of the experimental conditions.

Screening vs. not screening at 13 inches. At 13 inches, effects comparable to those at 20 feet were found. With screening, the average heterophoria was 4.78 prism diopters of exophoria; whereas, without screening, the average was 5.17 prism diopters of exophoria, or an increase of 0.39 prism diopters. This difference is statistically significant, and is the same in magnitude and direction as the shift observed at 20 feet when screening was omitted. (An increase in exophoria is the same in direction as a decrease in esophoria.)

The effect of screening is present with the rod before either the dominant or the nondominant eye, and with both colors of rods. When the rod is before the dominant eye, the change is 0.62 prism diopters; that is, from 4.71 with screening to 5.33 without screening; and when the rod is before the nondominant eye, the change is 0.17 prism diopters; that is, from 4.85 to 5.02. With the red and white rods, the changes are 0.21 and 0.59 prism diopters respectively (table 4).

It is necessary to specify, therefore, that screening be done or omitted throughout the routine testing of heterophoria, whether at 20 feet or at 13 inches.

Dominant vs. nondominant eye at 20 feet. The question of whether the Maddox rod should be placed before the dominant or the nondominant eye during heterophoria testing is one of long standing. Dolman⁵ suggested placing the rod before the nondominant eye on the basis of observations of 100 cases, 81 percent of

which revealed different heterophoria measurements when each eye was tested separately. He observed that 66 percent exhibited more heterophoria when the rod was placed before the nondominant eye; 7 percent had more with the rod before the dominant eye; and 17 percent gave identical figures regardless of which eye was behind the Maddox rod. Dolman made conflicting interpretations of these observations when he said "... it is evident . . . that the unequal degrees of deviation depend upon the fact that the role of fixation is given to each eye in turn. The stimulus received by the retina of the eye fixing the text object (fixation reflex) determines the direction of both visual axes when the other eye is screened."

When Dolman's data are subjected to statistical analysis, it becomes obvious that his conclusions, drawn on analysis of percentages only, are erroneous. Actually there is in Dolman's data no significant difference between results of testing with the Maddox rod before first the dominant eye and then the nondominant eye. Clinical testing for heterophoria varies in this respect. Placement of the Maddox rod before the dominant eye is recommended by many clinicians on the assumption that occlusion of the habitually fixing eye more completely disrupts fusion. Others routinely place the Maddox rod before the right eye, which means that the Maddox rod is before the dominant eye about 75 percent of the time.

No significant difference was discovered between heterophoria measures with the Maddox rod placed separately before either the dominant or the nondominant eye under any condition tested in this study. The average with the rod before the dominant eye was 1.50 prism diopters of esophoria, and before the nondominant eye was 1.62 prism diopters of esophoria. This similarity exists with or

without screening, and with the red or with the white Maddox rod.

Dominant vs. nondominant eye at 13 inches. There was no significant difference between heterophoria measured with the Maddox rod placed separately before either the nondominant or the dominant eye at 13 inches. When the rod was before the dominant eye, the average was 5.02 prism diopters of exophoria, and when the rod was before the nondominant eye the average was 4.92 prism diopters of exophoria. This similarity in heterophoria reading is present with or without screening, and with a red or with a white rod.

It does not appear necessary to designate whether the dominant or the nondominant eye shall be used in the routine testing for heterophoria, at 20 feet or at 13 inches. This conclusion is consistent with Dolman's⁵ data.

Red vs. white Maddox rod at 20 feet. The color of the Maddox rod used to measure heterophoria may be important in testing because the human eye is approximately 0.5 diopter hypermetropic for the color red.⁹ Thus the eye should accommodate 0.5 diopter more in clearly imaging a line seen through a red Maddox rod than one seen through a white Maddox rod. This increased accommodation should create an increased convergence tendency which may manifest itself as esophoria. Thus if a red rod is used instead of a white one, we may logically expect exophoria to decrease and esophoria to increase. A white rod should theoretically yield a more accurate measure for this reason. Another argument for the use of the white Maddox rod instead of the red one is that the white rod is usually far more optically accurate than the red by virtue of the production methods utilized for the two rods.⁵

In this study, changing from a red to a white rod was, on the average, equivalent to subtracting 0.25 prism diopters of

esophoria from the reading. With the red rod, the average reading was found to be 1.68 prism diopters of esophoria; with the white, it was 1.43 prism diopters of esophoria. The difference is statistically significant.

This difference due to color of the rod was found to exist when the rod was before either the dominant or the non-dominant eye. With the rod before the dominant eye, the change from a red to a white rod produced 0.30 prism diopters less of esophoria; with the rod before the nondominant eye, the change produced 0.20 prism diopters less of esophoria. Likewise, the difference introduced by the color of the rod persisted in the presence or absence of screening. With screening, the white rod gave 0.21 prism diopters less of esophoria than the red rod, without screening, the white rod gave 0.30 prism diopters less. The difference between the red and the white rod is a little less than the 0.50 prism diopters expected on theoretical grounds.

For routine determinations of lateral heterophoria, it appears to be important to specify the color of the rod which is to be used in the testing at 20 feet.

Red vs. white Maddox rod at 13 inches. Changing the color of the rod did not significantly change the heterophoria reading at 13 inches. With a red rod, the average was 5.08 prism diopters of exophoria, and with a white rod, 4.87 prism diopters of exophoria. This similarity was found both in the presence and absence of screening, and with either the rod before the dominant or the nondominant eye. For determinations of heterophoria at 13 inches, therefore, it does not appear to be necessary to designate the color of the Maddox rod.

The fact that the color of the Maddox rod makes a significant difference at a testing distance of 20 feet but none at 13 feet can be explained on logical grounds.

At 20 feet, the patient is using a minimum of accommodation and the increase of 0.5 diopter necessary to image clearly the red rod's line is sufficient to become manifest as an increase in esophoria. At 13 inches, however, a minimum of 3 diopters of accommodation is being exerted and the added 0.5 diopter necessitated by changing from a white to a red Maddox rod is not sufficient to become manifest as more esophoria.

CORRELATION OF MEASUREMENTS

Correlation between measurements of heterophoria at 20 feet. While an average increase of 0.37 prism diopters was introduced by the use of the screening, this amount of change did not occur exactly for each subject under each of the combinations of testing conditions. The high uniformity of the change, however, may be seen from product-moment coefficients of correlation in Table 6. The correlation coefficients between the screening and not screening measurements average about +0.90, which is equivalent to saying that knowledge of heterophoria determined without screening may be used to predict heterophoria with screening with a high degree of accuracy. Similar correlation coefficients for the red-rod versus the white-rod tests, and for the rod before the dominant eye versus the rod before the non-dominant eye likewise show high relationships for these testing conditions.

To facilitate transformation of heterophoria readings taken at 20 feet with screening into readings without screening, linear regression coefficients are included in Table 6. To illustrate the use of the regression coefficients, assume that a measurement of heterophoria was made on a single individual with a light at 20 feet and a red rod before the nondominant eye, using screening. Assume further that it is desired to transform this measurement into that expected if screening had not

been used. The regression of not screening on screening (b_{65} in table 6) is 0.98 for these conditions, which says that for each diopter change in heterophoria measured with screening, there is on the average 0.98 prism-diopter change in the same

The screen and parallax test using a light source at 20 feet from the subjects gave an average of 0.64 prism diopters of esophoria (table 7). This is about one diopter less than the average of the eight variations of the Maddox-rod tests. The meas-

FORMULA

$$\begin{array}{c} \text{Predicted} \\ \text{heterophoria} \\ \text{without} \\ \text{screening} \end{array} = \begin{array}{c} \text{Average} \\ \text{heterophoria} \\ \text{without} \\ \text{screening} \end{array} + \begin{array}{c} \text{Regression} \\ \text{of screening} \\ \text{on non-} \\ \text{screening} \end{array} \left[\begin{array}{c} \text{Observed} \\ \text{heterophoria} \\ \text{with} \\ \text{screening} \end{array} - \begin{array}{c} \text{Average} \\ \text{heterophoria} \\ \text{with} \\ \text{screening} \end{array} \right]$$

Taking the appropriate values for the conditions specified (red rod before nondominant eye), gives:
 $\text{Predicted} = 1.55 + 0.98 (\text{Observed} - 1.89)$

Assume that 4 prism diopters of esophoria were observed in a subject with screening. The predicted heterophoria for this subject without screening is 3.6 prism diopters of esophoria.

direction without screening. Substitution in the above formula will accomplish the desired transformation.

Correlation between measurements at 13 inches. The correlation coefficients for the intensity of the relationship between measurements at 13 inches are sufficiently high to enable accurate prediction from a measurement taken under one circumstance to a measurement taken under another (table 6).

Correlation of Maddox-rod tests with the screen and parallax tests at 20 feet.

urements of heterophoria by the eight variations of the Maddox-rod test correlate equally well with measurements made by the screen and parallax test. At first glance, there appear to be higher correlations between the screen and parallax test and all variations of the Maddox-rod test when the rod is before the nondominant eye than when the rod is before the dominant eye. The difference between the corresponding correlations was found to be nonsignificant (by z transformation). There is consequently no obvious advan-

ing) so far as the correlation with the screen and parallax test is concerned.

At this testing distance, the results in this experiment agree with those for a previous experiment summarized in Table 2, where the correlation between the screen Maddox-rod test and the screen and parallax test was found to be 0.81.

obvious choice among the variations of the Maddox-rod test at a testing distance of 13 inches (table 7). However, in this sample, the correlations are all higher than the correlation found in the previous experiment (table 2). No obvious explanation for this discrepancy has occurred to us.

NOTE ON STATISTICAL METHOD

These two experiments, at near and distance fixation, are factorial in type with three factors being tested at each of two levels. When it was found that the variances of heterophoria at 20 feet constituted a homogeneous set which was definitely different from the variances at 13 inches, the data for the two distances were kept separate. This made it possible to use the method of analysis of variance to detect the main effects of screening, eye dominance, and rod color, as well as the interactions of these factors. The results of the statistical analysis are summarized in Table 8, in which evidence is contained for each of the assertions about significance or nonsignificance of the difference made in the preceding sections.

The design of this experiment also makes possible an estimate of reliability of the measurement of heterophoria using the methods of internal consistency proposed by Hoyt.⁶ For heterophoria measured with a testing distance of 20 feet, the reliability coefficient was 0.976, and with a distance of 13 inches the coefficient was 0.975.

✓ SUMMARY

✓ 1. The reproducibility or reliability of measurements of heterophoria when taken by two examiners using the screen Maddox-rod test was found in one sample of aviation cadets to be satisfactorily high. The coefficients of reliability were +0.95 for lateral heterophoria and +0.92 for vertical heterophoria at a testing distance of 20 feet. In another sample, after removal of systematic effects due to the use of screening and to changing the color of the rod, the Maddox-rod test both at 20 feet and at 13 inches had a reliability coefficient of +0.97 for lateral heterophoria.

✓ 2. There is no significant difference in results obtained by two different examiners in administering the screen Maddox-rod test.

3. Several tests for heterophoria were compared with the screen and parallax test, which is considered the most accurate test. At a testing distance of 20 feet, a high correlation was found with von Graefe's prism diplopia test and with the screen Maddox-rod test. At a testing distance of 13 inches, a high correlation was found with von Graefe's prism diplopia test, the Maddox-wing test, and the Thorington test. The correlation with the screen Maddox-rod test was somewhat lower in one experiment, but high in another.

4. The effect of varying the testing conditions upon the Maddox-rod test was determined. The amount of illumination had no significant effect. It makes no difference whether the Maddox rod is placed over the dominant or the nondominant eye. At a testing distance of 20 feet, a red Maddox rod uncovers more esophoria than does a white one, but there is no difference between the effect of the red and white rods at 13 inches. With screening, the Maddox-rod test uncovers more esophoria or less exophoria than without screening.

5. The Maddox-rod test for all possible combinations of four alternative testing conditions was found to be highly correlated with the screen and parallax test.

6. The following conclusions may be drawn from the results.

a. Heterophoria measurements may be performed with sufficient accuracy to discriminate between individuals.

b. The Maddox-rod test gives results sufficiently like those of the screen and parallax test to be used as a replacement for it for purpose of routine testing.

c. It is recommended that the Maddox-rod test be performed with a white rod, without screening, and without regard to placing the rod before the dominant or nondominant eye for purposes of routine testing. ✓

ACUTE GLAUCOMA: A FOLLOW-UP STUDY*

H. SAUL SUGAR, M.D.

Detroit, Michigan

As part of an effort to emphasize the fallacy of fitting newer knowledge of glaucoma to an accepted classification, rather than fitting the classification to our newer views regarding glaucoma, I reviewed, in 1940, a series of 49 cases¹ of acute glaucoma. It was pointed out in that paper that an acute glaucomatous attack frequently starts without congestion and only after the vascular system of the eye no longer can tolerate the high tension and accumulation of metabolic products does congestion supervene. I concluded that the classification of acute glaucoma as congestive glaucoma is unjustifiable and suggested that the presence or absence of congestion be designated in an auxiliary diagnosis; for example, acute glaucoma—congestive phase, or acute glaucoma—non-congestive phase, as the case may be. A review of this same series of cases after a period of six years is presented, since it revealed further justification for the above conclusions, as well as rather interesting observations on

the course of acute glaucoma and the provocative tests for this condition. An addition to the therapeutic approach is suggested as a result of this study.

Since the case histories of the series were published in the original presentation, only those cases in which pertinent information has been added will be reviewed. In addition, a few cases not of this series are included in this paper to emphasize particular points under discussion.

Of the 49 patients in this series, four were instances of acute glaucoma due to lenticular intumescence. All of these were treated surgically and required no further follow-up from the viewpoint of this paper. Therefore, all of the following considerations will concern only the remaining 45 patients with "primary" acute glaucoma. Of these, 17 had had surgical treatment to both eyes at the time the original study was published. Four others could not be followed (cases 12, 19, 34, and 43). Thus, a total of 21 patients (46.6 percent) did not contribute to the follow-up study. Of the remaining 24 patients, 12 (cases 8, 10, 11, 17, 21, 29, 30, 31, 35, 36, 37, and 45) showed no significant

* From the Illinois Eye and Ear Infirmary, University of Illinois College of Medicine, and Michael Reese Hospital, Chicago. Under a grant from the W. K. Kellogg Foundation.

change from the time of the original study, and 12 (26.6 percent of the total) showed some significant change during the six-year follow-up interval. The latter are here reviewed in detail. The case numbers are the same as in the original, published study.

CASE HISTORIES

Case 2. This 44-year-old woman had experienced blurring of vision with the left eye during and after seeing motion pictures for two years before coming to the Illinois Eye and Ear Infirmary (hereafter referred to simply as the Infirmary). Occasionally, the blurring was accompanied by ocular pain, nausea, and vomiting. There was never any redness of the eye. During the same period, reading had caused enough discomfort to cause her to avoid it. Two days after being refracted under homatropine cycloplegia at the Infirmary in 1940, she awoke during the night with a headache. The eyes were not red. The following morning, the patient was nauseated and vomited, but the eyes were still pale. The patient went to the Infirmary the same day, where the tension in the left eye was found to be 60 mm. Hg (Schiotz). Miotics were promptly effective in reducing the tension to normal. Provocative dilatation of the right eye with a 2-percent homatropine-hydrobromide solution was ineffective in raising the tension in three hours.

In spite of the continuous use of pilocarpine instillations once daily, this patient experienced an acute attack of glaucoma in the left eye after an emotional upset on April 1, 1944. Pain was severe for 12 hours. The eye was pale. An iridencleisis operation was performed to relieve this attack. The tension was controlled thereafter with the use of pilocarpine. A repeated provocative dilatation of the right pupil with homatropine-hydrobro-

mide (2 percent) solution was ineffective in raising the tension in two hours.

Case 6. This 56-year-old man became aware of pain and blurred vision in his right eye in January, 1939, while playing cards. The eye was not red until the following morning. No treatment was sought for two weeks. Four weeks after the onset of the attack, examination at the Infirmary revealed a stony-hard eye which responded only to surgical treatment. Provocative dilatation of the left eye with paredrine for three hours was ineffective in raising the tension. Both chambers were shallow.

On June 15, 1942, the tonometric readings were: R.E., 24 mm. Hg (Schiotz); L.E., 77 mm., in spite of the use of pilocarpine. Vision in the left eye had become blurred two weeks previously. An iridectomy was done on June 25, 1942. The tonometric readings remained normal until the patient left the state in November, 1944.

Case 9. This 62-year-old woman began to notice halos and occasional headaches whenever returning home from attending a motion picture theatre in November, 1938. The eyes were never red, and the symptoms were always relieved by cold applications. In August, 1939, while on a trip, the right eye became painful, and later red. An oculist whom she consulted referred to the condition in a letter as acute glaucoma. The use of miotics was successful in relieving the attack within four hours after beginning treatment. On returning from the trip, the patient was seen at the Infirmary. Tension in the right eye was 80 mm. Hg (Schiotz), but the eye was not red. Miotics promptly reduced the tension to normal. A similar blurring and pain involved the right eye on April 15, 1940. The increased tension was promptly reduced to normal with miotics. The eye was not red.

Provocative dilatation of the pupil of

the left eye with paredrine and homatropine solutions was ineffective in causing an acute glaucomatous attack. The pupil could not be dilated beyond 4.5 mm. in $3\frac{1}{4}$ hours.

In spite of the continuous use of pilocarpine, this patient experienced another acute attack in the right eye on July 30, 1945. The tension was: R.E., 84 mm. Hg (Schiotz); L.E., 22 mm. Tension in the right eye was reduced to 31 mm. by the next day but it returned to 54 mm. three days later. On August 6, 1945, an iridencleisis was performed on the right eye. This, together with the use of pilocarpine, controlled the tension.

A repeated provocative dilatation of the pupil of the left eye with a 2-percent homatropine-hydrobromide solution was ineffective in raising the tension in two hours.

Case 15. This 60-year-old woman noticed blurring and pain in her right eye, followed by headache and vomiting, on November 3, 1939, after weeping. Three days after the onset, the ocular hypertension was reduced to normal with miotics. The left eye was unaffected. Provocative dilatation of the pupil of the left eye, in 1940, caused an acute ocular hypertension which was relieved quickly with one drop of 0.25-percent eserine. The eyes remained normal on miotic therapy until March 5, 1941, when this patient appeared after having had pain, redness, and decreased vision in the left eye for three days. The tonometric readings were: R.E., 20 mm. Hg (Schiotz); L.E., 80 mm. The tension was reduced to normal rapidly with 2-percent pilocarpine-nitrate instillations. This patient was able to seek private medical care so further follow-up was not possible.

Case 16. This man, aged 69 years, in 1941, experienced his first attack of glaucoma one afternoon in 1938. He had pain and headache on the left side of the

head. This was successfully relieved by the application of heat. Five days later, shortly after awakening, another attack occurred. The eye was not red until later in the day. The pain and blurring of vision which were present at the onset continued less severely for five weeks before the patient was seen at the Infirmary. Miotics were ineffective, and a trephining operation was successfully done on the left eye on February 25, 1938. The right eye had a tension of 52 mm. Hg (Schiotz) on July 3, 1940. This was promptly normalized with miotics. Provocative dilatation of the pupil of the right eye, in 1940, with paredrine and homatropine solutions was ineffective in raising the tension above 21 mm. Hg. However, on August 31, 1940, tension in the right eye was 53 mm. This was normalized with pilocarpine. Again, on April 29, 1942, tension in the right eye was 46 mm. and on June 10, 1942, while the patient had been using eserine (0.5 percent) the tension was 67 mm. An iridectomy was done on the right eye. The tension then remained normal until the patient's death in April, 1943.

Case 18. This 51-year-old woman experienced her first ocular symptoms in July, 1940, while viewing a movie. The eyes were not red, but the vision was blurred. Reading frequently caused blurring of vision. When first seen at the Infirmary in December, 1940, tension was: R.E., 70 mm. Hg (Schiotz); L.E., 46 mm. Both eyes were pale. Miotics caused reduction of tension to normal within 30 minutes. On December 21, 1940, after being asked not to use the prescribed pilocarpine in the right eye that morning, the patient's tension was 60 mm. in the right eye, and 28 mm. in the left. Miotics reduced the tension of the right eye from 60 to 24 mm. Hg within 20 minutes. Provocative dilatation of the pupil of the left eye with 2-percent euphthalmine on January 9, 1941, caused a rapid rise in ten-

sion from 28 mm. Hg to 60 mm., in 30 minutes. Repeated attacks of high tension in the right eye occurred on April 12, 1942, and on four occasions in February, 1944, despite the punctual use of pilocarpine and eserine, 5 to 8 times daily, as directed to do at various times. The eyes were always pale. This patient was put on a combination of 1-percent neosynephrine, 0.25-percent physostigmine salicylate, and 2-percent pilocarpine nitrate, 6 times daily. During a two-month period of observation, this patient experienced two attacks of hypertension, each of which was relieved after further instillations. This patient felt that the addition of neosynephrine was of some help; however, I could not be certain of its value in this case.

Case 22. This 45-year-old woman had experienced pain in her left eye about three times weekly for three years before being seen at the Infirmary in 1939. These episodes were sometimes associated with excitement and sometimes occurred after attendance at a motion-picture theatre. The pain usually lasted overnight and was never associated with redness of the eyes. On June 24, 1939, a homatropine refraction was done, following which the tension was found to be: R.E., 40 mm. Hg (Schiotz); L.E., 80 mm. The eyes were pale. Miotics reduced the tensions to normal within an hour. Provocative dilatation of the pupil of the left eye with 2-percent euphthalmine subsequently caused an acute ocular hypertension, yet the eye remained free of any injection. Tension rose from 26 mm. Hg to 57 mm. in 40 minutes.

On February 24, 1941, the patient experienced a sudden attack of pain, redness, halos, and headaches which lasted for two days before she was seen at the Infirmary. Tension was 68 mm. Hg (Schiotz) in the left eye despite the use of pilocarpine. This was relieved with miotics. On October 20, 1941, associated with

the serious illness of a close relative, the patient experienced another similar attack in the left eye. This was relieved by bilateral iridectomy-sclerectomies.

Case 23. This 50-year-old man noticed halos after seeing motion pictures two months before the onset of a severe attack of acute glaucoma. The halos disappeared by the following morning. The eyes were not red. On the night of December 19, 1940, the patient did not sleep well. At 10 o'clock the next morning the right eye was very painful and swollen. Miotics given the following day were ineffective in reducing the tension. An iridectomy-iridencleisis was performed on the fifth day. Two separate attempts to provoke acute glaucoma by dilatation of the pupil of the left eye with euphthalmine, paredrine, and homatropine solutions were unsuccessful. The pupil could not be dilated beyond 6.5 mm.

On December 30, 1944, the patient was awakened at 2:30 o'clock in the morning by pain in the left eye. He had been using doryl drops, three times daily. The eye was red and hard when seen at the Infirmary on January 1, 1945, when an iridencleisis was performed.

Case 24. This 57-year-old woman had noticed ocular discomfort after seeing motion pictures or after reading for several months previous to being seen at the Infirmary on February 21, 1938. A week before admission, her right eye was red and painful on awakening one morning. The symptoms continued for a week. When seen at the Infirmary, tension in the right eye was 60 mm. Hg (Schiotz). Miotics were ineffective in reducing the tension below 40 mm. An iridectomy was performed four days later. Provocative dilatation of the left pupil in April, 1946, caused an increase of tension from 23 to 39 mm. in 2½ hours.

Case 27. This 27-year-old man had experienced blurring of vision, pain, and often slight injection of the right eye in-

termittently about twice weekly since the age of 17 years. These episodes usually occurred after attending a motion-picture theatre or after reading, usually at night. On November 29, 1938, a homatropine refraction was done at the Infirmary. The pupil of the right eye never returned to its normal diameter. Two days after the refraction examination, the patient began to have pain and slight injection of the right eye. When seen at the Infirmary four days later, the tonometric reading for the right eye was 60 mm. Hg (Schiotz). The eye was very slightly injected. Miotics were ineffective in reducing the tension to normal. A trephining operation done on January 11, 1939, on the right eye was unsuccessful. It was followed on February 8, 1939, by cyclodialysis of the right eye. This was successful. The cleft was visible gonioscopically. However, nearly four years later, on December 8, 1942, tension in the right eye was elevated to 52 mm. Hg (Schiotz). On eserine therapy, the tension returned to normal and has remained normal since on miotics. The cyclodialysis cleft is open but shallow.

This is probably the youngest case of true acute glaucoma on record, having started with prodromata at about the age of 17.

Case 32. This 73-year-old man awoke one morning with blurring of the vision of the right eye, slight injection of that eye, and slight headache. He went to the Infirmary the next day, after the eye had become worse. It was then red and the tension was 70 mm. Hg (Schiotz). Miotics were only temporarily effective. A trephining was done in October, 1940. Provocative dilatation of the pupil of the left eye was ineffective in causing glaucoma. The pupil could not be dilated beyond 5 mm. In June, 1946, this patient was sent a card requesting his appearance for examination as a part of this study. When seen, the eyes were pale. Tension in the right eye was well controlled. Tension in

the left eye was 60 mm. Hg (Schiotz). The retinal arteries pulsated. The tension was reduced to 27 mm. within one hour after instillation of a drop of 0.5-percent eserine. The patient stated that he had seen halos during the past two months. The eye had never been red. He had not used miotics for several months.

Case 40. This 60-year-old man experienced aching of the right eye without blurring of vision or redness of the eye one evening after supper in July, 1939. He awoke the next morning with the right eye red and its vision blurred. Three or four days later he consulted a physician, who referred him to the Infirmary. The tension in the right eye was 82 mm. Hg (Schiotz). Miotics were ineffective. An iridotaxis was performed on August 12, 1939. Provocative dilatation of the left eye with paredrine and homatropine solutions for three hours caused no increase in the tension. The pupil did not dilate beyond 6 mm. The miotics were stopped after the operation on the right eye.

On January 28, 1945, the patient experienced a typical attack of acute glaucoma in the left eye. Miotics were effective in reducing the tension to normal. On March 1, 1945, in spite of the use of miotics, the patient experienced another such attack in the left eye. On March 10, 1945, a left iridencleisis was done.

DISCUSSION OF THESE CASES

The discussion of these cases will be considered under two main headings: I. The relation of acute glaucoma to narrow-angle glaucoma in general. II. Miotics in acute glaucoma.

I. THE RELATION OF ACUTE GLAUCOMA TO NARROW-ANGLE GLAUCOMA IN GENERAL

In recent years, there has been a tendency to substitute the term *narrow-angle glaucoma* (Barkan) for the previous classification of acute and chronic-congestive

glaucoma. This is a definite advance in our thought and helps avoid the inclusion of a description of the vascular reaction of the eye in the diagnosis. Yet the terms are, strictly speaking, not synonymous, since narrow-angle glaucoma covers a wider range of cases:

1. Classical "acute congestive glaucoma"
2. "Chronic congestive glaucoma"
3. Dilatation glaucoma
4. "Preglaucoma"
5. Acute glaucoma due to lenticular intumescence
6. Acute glaucoma due to dislocation of the lens into the anterior chamber
7. Mixed glaucoma (including acute glaucoma as one form)

I, therefore, do not ordinarily use the term but prefer to include the first four conditions listed above in the term "primary" acute glaucoma and to consider the others separately. Demonstrations of the relationship between the first four is the basis of this grouping and is one of the purposes of this paper.

The fallacy of using the terms congestive and noncongestive as part of the diagnosis has already been pointed out.¹ In the follow-up study herein described, three (cases 2, 18, and 32) of the 11 patients with spontaneous attacks of acute glaucoma had no externally visible ocular congestion. One patient (case 32) was found only accidentally to have an obstructed angle and acute glaucoma. He had no complaints. The eye was not red. In Case 18 the angles were so shallow that on previous occasions it was possible to bring the intraocular pressure quickly to a high level simply by avoiding a single instillation of the miotic being used. The clinical picture and history in Cases 2 and 18 were typical of "acute congestive glaucoma," in that they had spontaneous attacks of high intraocular pressure and shallow angles which became obstructed,

but atypical in the absence of congestion. By avoiding the term describing the absence or presence of congestion, these cases can be properly classified.

The confusion is emphasized in Case 17 in which a woman, then 44 years of age, had an acute glaucomatous attack in the right eye in January, 1935. The eye was not red. It was treated surgically. The diagnosis was acute glaucoma. Five years later, during a study of the other eye, the resident, in reviewing the original history of the acute episode, made a note on the hospital record stating that the original diagnosis must have been incorrect because the eye had been pale, and that the diagnosis should have been "chronic compensated glaucoma." That the diagnosis of acute glaucoma was correct is shown by the presence of a typical cataracta glaucomatosa acuta (Glaukomflecken of Vogt) in the right eye.

The relationship between the congested and noncongested eyes with acute glaucoma will be further demonstrated in the discussion of the relationship between the first four groups listed above.

The Relationship between Acute Glaucoma and Chronic Congestive Glaucoma.

I consider "chronic congestive glaucoma" to be a form of ordinary acute glaucoma in which the episodes recur repeatedly and then subside. When one of the attacks persists, it is considered, of course, an acute attack, but it is in the prodromal period that diagnostic confusion appears. In going over the records of this series of 45 cases of acute glaucoma, 24 were found to have had prodromal episodes. Some had been diagnosed as chronic congestive glaucoma during one of the prodromal attacks while others, in whom the episode was still in a noncongestive phase, were called "chronic compensated glaucoma" (which I have always considered to be synonymous with

glaucoma simplex). However, when an ultimate acute persistent attack occurred in these cases, the diagnosis then became acute glaucoma.

An example will suffice. B. M., a 66-year-old man, in 1939, first noticed episodes during which he experienced decreasing vision, headaches, and saw rainbows about lights, in 1937. He finally had an acute glaucomatous attack, with slight injection of the left eye, in June, 1939. This was successfully treated by trephination. The case history was not included in the original series of cases only because the diagnosis of "chronic incompenstated glaucoma" had been made. Tension in the right eye remained below 15 mm. Hg (Schiotz) on five examinations from October, 1940, through March, 1941. Then, on April 15, 1941, a typical acute attack occurred in spite of the continuous use of pilocarpine. The eye did not respond to pilocarpine and eserine. A trephination was successfully performed. This case demonstrates the fact that our separation of "acute" and "chronic congestive glaucoma" has been an artificial one.

The Relationship between Acute Glaucoma and Dilatation Glaucoma.

During the period when I was privileged to organize the Glaucoma Clinic at the Illinois Eye and Ear Infirmary at the instigation of, and under the direction of, Dr. Harry S. Gradle, several instances occurred in which, after the use of cycloplegics for refraction, the ocular tension was found to be elevated to 60 mm. Hg (Schiotz) or more. The eyes were pale, and, except for pulsation of the retinal arteries, which were clearly visible, no other abnormalities were evident. The use of pilocarpine or eserine promptly brought the tension down to normal. Attempts at classification led to the same difficulties previously mentioned because of the lack of congestion. Most of these

cases were incorrectly diagnosed as "chronic compensated glaucoma" for lack of a better designation in the classification in general use.

The relation between these two types of cases is shown in this series of cases. Six had typical spontaneous acute glaucoma in one eye, and acute glaucoma following dilatation for refraction, examination, or accidentally, in the other eye (cases 1, 7, 8, 14, 36, and 41). The histories of the presence or absence of congestion indicated that, in all instances where dilatation was the cause of the acute attack, the eye was pale for one to two days before the pain and redness began. More specific relationship between the two groups is evident from the history in Case 2 in which one eye first had an attack of acute glaucoma following dilatation of the pupil before refraction, and four years later, the same eye was involved in a spontaneous attack.

I am convinced that there is no difference in the pathologic conditions in spontaneous typical acute glaucoma and acute glaucoma following dilatation. Here again the absence of congestion should be of no significance in the classification. If the situation is recognized during the early noncongestive phase and the tension is relieved by miotics, there is difficulty in calling the condition "acute congestive glaucoma." However, if the eye is seen after a longer period and is in a congestive phase, that term would fit.

The cases of glaucoma following provocative dilatation fall into the same classification. In the series considered here, two cases (24, 15) had spontaneous attacks of acute glaucoma in one eye and high tension following provocative dilatation in the other eye. In one of these, a spontaneous attack later occurred in the eye which had shown a positive provocative test. In three other cases, the same eye had a spontaneous acute attack which

was relieved and subsequently showed a positive provocative test (cases 18, 29 and 37). Since these cases were under observation at the time of the tests, the tension was brought back to normal during the noncongestive phase. If they had been allowed to remain at the high tension, some would undoubtedly have passed into the congestive phase. In Case 8, a provocative test was done with euphthalmine. The tension was 15 mm. in each eye. After one hour it was 18 mm. in each eye. The test was correctly considered to be negative by the resident, and the patient allowed to leave, but without instilling a miotic. The next day a typical congestive attack began in the right eye, requiring surgery.

As a result of the findings in the provocative tests, I pointed out in 1941² that provocative tests for glaucoma may be divided into two groups. One group for eyes with normal anterior-chamber depth—the caffein test (in my experience of little value), the drinking test, and the anterior-chamber puncture tests, in the order named. In another group of tests for eyes with shallow chambers and angles, the dark-room test should be done first, followed by a mydriatic test with 2-percent euphthalmine. If negative, 1-percent paredrine is then used, and, if still negative, homatropine. I pointed out that negative results from these tests are of no significance. In the series considered here, four patients had negative responses to provocative dilatations (cases 16, 23, 32, 40) but later had spontaneous acute attacks. Three of the four (cases 16, 23, and 32) had been examined gonioscopically before, during, and after mydriasis. The angles were patent but very narrow. The gonioscopic findings in these cases, as well as the majority of the other provocative tests, were previously mentioned.¹ Pointing out the relationship between positive provocative pupillary dilatation and acute

glaucoma has the disadvantage of emphasizing this particular mechanical aspect of acute glaucoma. One must not lose sight of the neurovascular congestive factor which is more important in spontaneous acute glaucomatous attacks.

The Relationship between Acute Glaucoma and "Preglaucoma."

Gradle's recent paper³ entitled "Preglaucoma" considers the term to include two forms: "first, the acute, shallow-angle type with the manifestations of acute decompensation; and second, the chronic, deep-angle form." In the case of the shallow-angle type, I believe that, during the normal interval between episodes, the term "preglaucoma" is correctly applicable, since at that time the eyes are entirely normal in their drainage mechanism. However, to call any phase of simple glaucoma "preglaucoma" is, in my opinion, not in keeping with our ideas regarding this condition, since in simple glaucoma the tension, whatever it is, is too high for that particular eye. At no time, then, are we sure that we are not dealing with active simple glaucoma. To avoid confusion, I believe the term should be used only in reference to an eye with potential acute glaucoma. Perhaps the term might better be "pre-acute-glaucoma."

Mixed Glaucoma.

Because one is dealing with a particular type of glaucoma, there is no reason why acute glaucoma may not be superimposed, if the anatomic predisposing factors are present. An elderly patient with simple glaucoma over a period of years does gradually get some shallowing of the chamber due to the increasing lens size. If the same patient has the anatomically (relatively) shallow chamber to begin with, he may develop an acute attack spontaneously or following dilatation. Similarly, patients with other forms of glaucoma may de-

velop a superimposed true acute glaucoma. Two cases of capsular exfoliation, with superimposed acute glaucoma follow.

J. F., a 71-year-old man, in 1939, suddenly noticed poor vision in the right eye in September, 1939. He was seen at the Infirmary where the tension was found to be 60 mm. Hg (Schiotz) in the right eye. The anterior chambers were shallow. Es-erine rapidly brought the tension to 32 mm. Typical capsular exfoliation was present in the right eye only. The right lens was removed because of cataract. The tension remained slightly above normal in spite of an open angle. This was considered characteristic of "glaucoma capsulare." In March, 1946, the patient was being prepared for removal of a cataract from the left eye, the one without capsular exfoliation. Preoperative dilatation of the left pupil caused an elevation in tension from 25 mm. to 49 mm. Hg (Schiotz) in two hours and return to upper normal after administration of es-erine. A subsequent water provocative test to help rule out the possibility of simple glaucoma was negative.

C. C., a 66-year-old man, in 1940, experienced a sudden attack of acute pain in his left eye and noticed rings around lights on May 18, 1940. This patient was seen at the Infirmary four days later. The tonometric readings were: R.E., 25 mm. Hg (Schiotz); L.E., 73 mm. All the findings of a congestive attack of acute glaucoma were present in the left eye. Both anterior chambers were shallow. Capsular exfoliation was present in each eye. The left eye did not respond to miotic therapy and on May 27, 1940, an iridectomy was performed on this eye. The tension remained normal thereafter.

The possibility of acute glaucoma superimposed on another type of glaucoma, especially simple glaucoma, should be kept in mind. However, in the case of simple

glaucoma, it is often very difficult to be certain that a mixed type is really present. An example of what I consider to be a probable case follows:

Mrs. L. F., aged 58 years in 1945, was first seen at the University of Illinois Eye Clinic on July 18, 1945. Her corrected visual acuity was 20/20 in each eye. The right peripheral visual field with a 5 mm. white target at 170 mm. was constricted to 55 degrees, temporally; 45, superiorly; 35, nasally; and 25, below; with a nasal step to 5 degrees in the upper nasal quadrant. The left field was constricted slightly to 65 degrees, temporally; 40, above; 50, nasally; and 50, inferiorly. The anterior chambers were shallow. The tonometric readings on August 20, 1945, were: R.E., 35 mm. Hg (Schiotz); L.E., 31 mm. A diagnosis of glaucoma simplex was made and treatment with pilocarpine instillations instituted. However, the tension stayed up, reaching 42 mm. in the right eye and 47 mm. in the left, on November 28, 1945. In January and February, 1946, the tension remained normal on pilocarpine. In May, the patient was started on di-isopropyl fluorophosphate (0.05 percent) in the right eye. The tension remained normal until May 27, 1946, when the tension was: R.E., 30 mm.; L.E., 21 mm. on June 1st, the tension was 39 mm. in the right eye; 20 mm. in the left. A drop of 0.1-percent D.F.P. was instilled. On June 3rd the tension was: R.E., 50 mm.; L.E., 23 mm. Gonioscopy at this time showed such a narrow angle in the right eye that the trabecular wall could not be seen. The patient was returned to pilocarpine therapy, and the tension was reduced. In July, the patient was seen again with an acute attack of glaucoma in the right eye. An iridectomy was performed.

II. MIOTICS AND ACUTE GLAUCOMA

It appears rather significant that approximately 27 percent of a series of

cases of "primary" acute glaucoma should show some important change over a period of only six years, particularly since most of the patients (8 of the 12) continued to use miotics during that time. The percentage of cases with significant change is much greater (50 percent), if one considers only the unoperated cases and those available for follow-up study. The findings in the series are shown in Table 1. In Case 2, the patient could not

be considered to have been on adequate amounts of miotics. In Cases 9, 18, 22, and 23, the patients were questioned carefully to be certain that one or more instillations of the drug had not been missed on the day of the acute episode. In the three other cases, this may possibly have been what happened.

The question arises: Why, especially in view of the continued use of miotics in most instances, should patients develop

spontaneous acute glaucoma even when previous provocative dilatation of the pupil was ineffective in elevating the tension? There are several phases to the answer to this question.

First, as we have already shown,⁴ patients with the anatomical predisposition to acute glaucoma become even more predisposed with the passage of time. The anatomic predisposition is due to relative shallowness of the angle of the anterior chamber which results from shortness of the eyeballs (usually manifested in hyperopic refractive errors), increased thickness of the iris or, occasionally, an abnormally small cornea and anterior segment. It has been shown⁴ that there is a relationship between refractive error and anterior-chamber depth in normal eyes. In the series of cases of acute glaucoma reviewed here, I found that hyperopic error was predominant as might be expected with shallow chambers. However, this series was too small to determine this factor accurately. I, therefore, studied a series of 140 eyes with acute (narrow-angle) glaucoma* in which the refractive error was recorded. These had an average hyperopic error of 2.72 diopters. Of the 140 eyes, only seven had myopic errors, the spherical equivalents of which were -4.75, -3.62, -2.62, -2.12, -0.50, -0.12, and -0.12 in patients aged 80, 80, 73, 70, 70, 68, and 37, respectively.

The time factor results from the gradual but constant increase in thickness of the crystalline lens as new lens fibers are added. This tends to increase the shallowness of the anterior chamber. Eventually a point is reached where miotics alone keep the angle free (as in Case 18). Finally, even miotics may be ineffective but, fortunately, such cases are infrequent.

* Taken in most instances from the records of Drs. Harry S. Gradle and S. J. Meyer who kindly permitted the use of their material.

The second factor involved in the answer to our question is the congestive effect of the miotic drugs. The fact that the same drugs are used for both acute and simple glaucoma has led to the false inference that the pathologic findings in both conditions are the same. These drugs have two effects, miosis and vasodilatation.⁵ The miotic action is the one which we seek in acute glaucoma while the vasodilatation effect is that sought in simple glaucoma. However, the vasodilatation factor is a disadvantage in cases of acute glaucoma where the congestion further embarrasses the already too narrow angle entrance.

Troncoso, in a recent review of Busacca's *Elements de gonioscopie normale, pathologique et experimentale*,⁶ stated that "Busacca still clings to the opinion of Salzmann, who stated the belief that atropine enlarges the chamber sinus and physostigmine narrows it. Sugar has shown that the converse is true."

Actually, I have pointed out only that the converse is *also* true. The effect of either drug on the angle depends on the interplay of two antagonistic actions of each drug. Physostigmine tends to narrow the angle by its vasodilating and its cyclotonic action but at the same time tends to open the angle by constricting the pupil. Atropine tends to widen the angle by its mechanical decongestive action but simultaneously tends to narrow the angle by increasing the iris thickness through folding.

The congestive effect of the miotic drugs is also evident clinically in patients with acute glaucoma in whom the attack is relieved by the miotic drug, but in whom, shortly afterwards, a reactive phase of increased intraocular pressure ensues, in spite of the continued use of powerful miotics. Case 9 is an instance of this. Another typical example of this follows:

Mrs. O. H. N., aged 51 years, was hospitalized at the Michael Reese Hospital in August, 1938, because of bilateral acute glaucoma. Instillations of 1-percent pilocarpine rapidly brought the tension down to less than 20 mm., but about 24 hours later tension in the right eye re-

probably also the reason why pilocarpine or eserine are not always effective in preventing the onset of an acute attack in the hitherto normal fellow eye of a patient who has just had, or recently had, surgical treatment for acute glaucoma in one eye.

Chart 1 (Sugar). Case of Mrs. O. H. N. Instillations of 1-percent pilocarpine rapidly brought the tension down to less than 20 mm. Hg, but about 24 hours later tension in the right eye returned to 60 mm. Hg shortly after the instillation of a 2-percent pilocarpine nitrate. By the following morning it had returned to normal. (— Right Eye. --- Left Eye).

turned to 60 mm. Hg (Gradle-Schiøtz) shortly after the instillation of a 2-percent pilocarpine nitrate. However, by the following morning it had returned to normal. The tonometric readings are shown in Chart 1.

The congestive effect of the miotics is

Two interesting examples of such instances follow:

Mrs. J. P., aged 59 years, was examined in 1941 at which time she was found to be 3.75 diopters hyperopic in each eye. The tonometric readings (Schiøtz) were 22 mm. Hg in the right eye, and 20 mm.

in the left, an hour after euphthalmine dilatation. About the end of March, 1946, this patient began to have headaches on the left side. The left vision was blurred. An antiglaucoma iridectomy was done on the following day. On April 10, 1946, I saw this patient for the first time. The tonometric readings were: R.E., 20 mm. Hg (Gradle-Schiøtz); L.E., 22 mm. Pilocarpine nitrate was ordered for instillation in the other eye as a prophylactic measure. The next morning the patient experienced an acute glaucomatous attack in each eye which required surgery.

Mrs. L. F., aged 57 years, had had episodes of dimness of vision during which she saw halos about lights for five years. When she was seen in 1936, the tonometric readings were: R.E., 50 mm. Hg (Schiøtz); L.E., 26 mm. A cyclodialysis was done on the right eye. Eserine was instilled into the left eye. At 3 o'clock the following morning the patient began to have severe nausea. By eight, the left eye became very painful. The tension was 73 mm. Hg (Schiøtz). It did not respond

to miotics and a left iridectomy was done.

The obvious solution to the problem is the addition of a vasoconstrictor drug to the miotic to be used *only* in patients with shallow angles who show evidence of potential or prodromal acute glaucoma or an actual acute attack. To test the effect of such a combination of drugs I studied the duration of action and the effect on the pupil of 0.1-percent prinine hydrochloride, 1-percent neosynephrine and a combination of 2-percent pilocarpine nitrate and 1-percent neosynephrine on a small series of patients, with normal eyes, between the ages of 42 and 68, the age group usually affected by acute glaucoma. The results are shown in Table 2.

The findings indicated that 0.1-percent prinine and 1-percent neosynephrine have an effect on the pupil for about 3 or 3½ hours. The combination of 2-percent pilocarpine and 1-percent neosynephrine mainly manifests the pilocarpine effect which is dominant and usually "covers" the pupil-dilating effect adequately.

The combination of 2-percent pilocar-

pine and 1-percent neosynephrine was then used for studies on glaucoma patients. The choice of drugs is empirical. Other stronger miotics and vasoconstrictor combinations possibly would be better since pilocarpine is a rather weak vasodilator. The ideal would be a single

drug with both effects. I know of no such drug, however. The recent reports of increased tension with the new drug D.F.P.⁸ suggests that occasional instances of angle blockage resulting from vasodilatation and cyclotonia might be prevented by the addition of a vasoconstrictor.

The combined drug was compared with 2-percent pilocarpine alone in 13 patients with early simple glaucoma to determine whether or not the vasoconstricting factor would cause elevation of the intraocular pressure. Each patient had discontinued the use of his own miotic drugs the previous night. The findings are shown in Table 3. In 12 of the 13 cases no difference was found in the two eyes. In the remaining case (8), the combined drug caused an increase in tension from 26 to 31 mm. Hg (Schiotz) and definite pupillary dilatation.

The combined drug was then given to 10 patients with narrow-angle glaucoma of the "pre-acute-glaucoma" type, as a substitute for the miotic drug being used. The drug was used for 4 to 6 weeks in each instance without untoward effect. Each of these patients had previously had provocative tests with mydriatics. Only one had responded with abnormal tension. He was included in the group given the combined drug. Tension in this patient's eye rose from 23 mm. Hg (Schiotz) to 45 mm. in one hour after instilling one drop of each of 2-percent neosynephrine and 1-percent paredrine. There had been no rise of tension with pilocarpine-neosynephrine.

Actually to prove that the combination of drugs is better than the miotic alone, one would have to show that the mixture was more easily able to control patients with narrow angles who are barely controlled by a miotic alone. By the very nature of the condition this would be practically impossible to prove unequivocally. (See Case 18.)

Serr⁷ studied the effect of pupillary dilatation and such drugs as pilocarpine, cocaine, and adrenalin in two cases of narrow-angle glaucoma (he designated them only as primary glaucoma and did not distinguish between simple glaucoma and acute glaucoma as separate entities).

He concluded that there is a definite threshold value of pupil diameter beyond which in each particular glaucomatous eye, the angle will be blocked; also that the vasoconstrictors such as cocaine and adrenalin decrease intraocular pressure in glaucomatous eyes by first decreasing the blood volume content of the globe and then by diminishing the secretion of aqueous by a toxic effect on the ciliary epithelium. He mentions that, by simultaneous use of adrenalin and miotics, a marked lowering of tension can be brought about. From my work with provocative pupillary dilatation in acute glaucoma, I believe that Serr's idea of a definite pupil threshold is correct only for a particular circumstance and that, under varying circumstances, the threshold changes. In spontaneous acute glaucoma where a congestive factor is usually present, the pupil width necessary to increase the intraocular pressure is much less than in dilatation glaucoma. Similarly, I believe that the vasoconstrictors are effective in narrow-angle glaucoma by decreasing the iris thickness, thus tending to open the angle. I know of no evidence that the secretion of aqueous is decreased by the vasoconstrictor drugs in the human eye.

The combination of miotic and vasoconstrictor drugs is suggested as a possible aid in the treatment of the acute (narrow-angle) type of glaucoma. It is not intended as a substitute for surgical therapy. In patients suffering from a congestive attack, the vasoconstrictor drug should be used in addition to eserine or any of the other strong miotics. In the treatment of patients with narrow-angle glaucoma in the noncongestive phase, the combined drugs should not be prescribed for home use until the effect on the pupil and tension have been observed by the oculist. Since the combined effect usually lasts only about three hours,

it may be necessary to instill the drugs more frequently than when pilocarpine alone is used.

CONCLUSIONS

1. In a series of 45 patients with "primary" acute glaucoma followed over a period of over six years, 26.6 percent showed some significant change during the follow-up period.

2. From a clinical point of view, classical "acute congestive glaucoma," "chronic congestive glaucoma," dilatation glaucoma and "preglaucoma" are all so intimately related as to constitute various clinical phases of the same condition.

The inclusion of descriptions of the vascular reaction of the eye in the main diagnosis is unjustified.

3. True acute glaucoma may be superimposed on other forms of glaucoma such as glaucoma capsulare and, unquestionably, even upon simple glaucoma.

4. Miotic drugs used in the treatment of acute glaucoma have the disadvantage of adding a congestive angle-narrowing factor where the angle is already anatomically too narrow. A combination of miotics with vasoconstrictors is suggested as a new approach to the therapy of acute glaucoma in all its phases.

ARACHNODACTYLY (MARFAN'S SYNDROME) ASSOCIATED WITH ECTOPIA LENTIS

REPORT OF A CASE WITH PIGMENTATION OF THE CORNEA

J. V. CASSADY, M.D., AND CORLEY B. MCFARLAND, M.D.
South Bend, Indiana

The clinical picture of Marfan's syndrome is that of a tall, thin individual with a saddened facies. His mobility is impaired because of muscular atrophy and faulty vision. Congenital defects are common and may involve the heart, joints, ears, lungs, ascending aorta, and palate. The muscular weakness has occasioned some investigation, and the usual finding is a normal reaction to electrical stimulation save that the response of the muscle is proportionate to the muscular atrophy.

Ocular changes are noted in about 60 percent of the cases, and include ectopic lenses, miosis with feeble or absent reaction to mydriatics, iridodonesis, variation in the intraocular pressure, divergent squint, myopia, coloboma of the lens, a thickened lens capsule, and megalocornea.

X-ray studies of the skeletal system reveal increased length of the metacarpals and phalanges, while the terminal phalanges are relatively more elongated. The long bones show no pathologic change other than elongation. Kyphosis and scoliosis are frequently observed, but perhaps this is due to relaxation of the ligaments.

Laboratory studies are usually non-revealing, save for alteration of the cytologic elements of the blood which occurs concomitantly with the associated congenital heart or pulmonary disease. The blood pressure and the basal metabolic rate are characteristically low in this asthenic type.

Marfan,¹ the French physician, in 1896, gave the first description of the syndrome which bears his name. In this presenta-

tion, his patient was a 5½-year-old girl who had long, slender feet and hands, elongated long bones, underdeveloped skeletal musculature, contractures of the joints, and retardation of the locomotor function. For this syndrome, Marfan selected the term *dolichostenomelia* to describe the feet and hands as being spider-like in configuration. In 1902, Méry and Babonneix² submitted the first roentgen study of the malshaped extremities of Marfan's original case, and suggested the term *hyperchondroplasia* in contrast to *achondroplasia*, because they noted enlargement of the cartilaginous portion of the epiphyses. Achard,³ in 1902, presented the second case to appear in the literature, and first used the term *arachnodactyly* to indicate that the feet and hands were spiderform in shape. This term has been given preference in the literature despite Marfan's initial use of *dolichostenomelia* to describe the shape of the hands and feet. Since Marfan's original description, Rados,⁴ in 1942, listed 204 cases which had been described through the year 1939.

The earliest description of the ocular changes is credited to Salle,⁵ who, in 1912, noted the presence of narrow pupils, shallowness of the anterior chamber, and normal optic papillae. Ormond and Williams,⁶ in 1923, added iridodonesis and dislocation of the lenses to the ocular findings.

The origin of this disease is entirely speculative. Dvorak-Theobald,⁷ in presenting the original histopathologic study of an eye from a patient who suffered from Marfan's disease, indicates that the

aberrant process is first noted about the fourth embryonic week, at which time, according to Ida Mann,^{8,9} the size of the mesodermal elements is determined by the presence of the optic vesicle. At this time some excitant is postulated by Dvorak-Theobald which causes megaloglobus. About the sixth fetal month, there is a suppression phase during which time growth and development is limited, and the trabecular tissue, dilator muscle of the iris, and pars iridica retinae are affected. It might be assumed that the skeletal abnormalities may be due to the same excitant and depressant action. Ida Mann, quoted by Morard,¹⁰ remarks that the "disturbances in Marfan's syndrome are probably only coördinated symptoms of a genotypic affection, producing general and ocular troubles which affect not only the mesoderm but the endocrine glands and ectoderm as well." In Burch's¹¹ paper, Mann further reflects that "one has to remember that various factors may account for the linking of defects. In the first place, the defect may be in a certain chromosome. Since the chromosome carries many genes mediating many different characters in various parts and various tissues, it is to be expected that superficially unrelated characters may be found to be related by their genic position in the blastomeres. There is no evidence to lead us to suppose that mesodermal and ectodermal structures are segregated in different chromosomes, and there is no inherent reason why the characters for the extremities should not be carried by the same chromosomes as certain eye characters."

The histopathologic findings as described by Dvorak-Theobald⁷ include megaloglobus, replacement of the dilator fibers of the iris by a "pink staining substance adjacent to the ectodermal pigment cells, incomplete formation of the pigment cells of the pars iridica retinae about half way between the iris border

and the base of the ciliary body, faulty placement of the angle of the anterior chamber in that it is anterior to the canal of Schlemm, faulty development of the circular muscle of the ciliary body, and elongation of the zonular fibers, allowing the lens to assume a spheroid shape."

One of the most interesting aspects of this syndrome is the hereditary and familial tendency; about 30 percent of all cases reported manifest such characteristics. While Stewart¹² and Moore¹³ have listed cases which occurred sporadically, it is generally agreed that arachnodactyly follows the Mendelian Laws, and Duke-Elder¹⁴ states that it is a dominant characteristic.

Marfan's syndrome is so well known in the ophthalmic literature that the presentation of just another case would not be of unusual significance. In the case herewith presented, however, one finds some very unusual features. The patient, a white man, aged 52 years, first came under the observation of one of us (J. V. C.) in January, 1946. He had been blind in the right eye since he was 14 or 15 years of age but, until two weeks before admission, had been able to see with the left eye by use of a cataract-thickness lens. At that time, he observed that a film seemed to have "dropped from above," blurring his vision except when he held his head down and looked "from under a curtain."

The patient was one of eight siblings whose mother was described as a tall, thin woman who wore thick correcting lenses. Four of the children were said to be normal, with no ocular complaints, whereas four had symptoms of Marfan's disease (fig. 1).

A sister, 55 years of age, had typical arachnodactyly. On ocular examination, she was found to be blind with glaucoma in each eye, which condition dated from an attempted cataract extraction at 13

years of age. A brother, aged 45 years, was not available for examination, but was described as being thin, with long hands and feet, having trouble with his eyes, and wearing very thick lenses. A younger brother, aged 38 years, was at home, having just received a medical discharge from the Army after being in several Army hospitals for eye examination. His ocular abnormalities were discovered in the Army when he was having a foreign body removed from his eye. He had dislocated lenses, arachnodactyly, iridodonesis, wore size-11 shoes, had high patellas, a sad countenance, and the dolichocephalic head of Marfan's syndrome. The fourth affected member of the family is the patient described. The other four children,

Fig. 1 (Cassady and McFarland). From left to right: the patient, his sister and brother; all with Marfan's syndrome, arachnodactyly and ectopia lentis.

their children, and one available grandchild were normal. Fortunately, three of the four afflicted individuals lived together and remained single. The fourth was married, but had no children.

Physical examination of the patient showed a tall, thin, doleful man of about 50 years of age. He had a dolichocephalic head with prominent supraorbital ridges and bossing of the frontal eminences. Sub-

cutaneous fat was absent, and there was a flaccidness to his muscular development. There was a striking hypotonicity of the thin muscles of his arms and legs. He had long extremities, spiderlike fingers and

Fig. 2 (Cassady and McFarland). This eye shows a yellowish-brown, granular, elevated, band-shaped corneal degeneration.

toes, high patellas, a flat chest, and excessive curvature of the soles of his feet.

The right eye (fig. 2) presented the unusual feature of this patient. There was a golden-yellow, band-shaped opacity involving most of the cornea of the right eye, extending horizontally from limbus to limbus. The surface was granularly elevated like crocodile leather. There was a strip of clear cornea above and a smaller strip inferiorly; clear, that is, except for the superficial vessels to the degeneration. On closer inspection, the vascularization was from the conjunctival vessels running in from all meridians to divide arborescently and interdigitate among many small vesicles. With slitlamp examination, a transparent-droplet formation was seen piled upon the corneal surface. On retroillumination, each vesicle was outlined by a pigment ring. On diffuse illumination, the pigment formation imparted a honey-yellow color to the granular band-shaped corneal degeneration. The iris, where it was visible above, showed iridodonesis but no evidence of inflammation, degenera-

tion, or vascularization. The eye was glaucomatous, and had been blind since the patient was about 15 years of age.

On external examination of the left eye, the cornea was clear, the pupil small, round, and regular. With ocular excursion, iridodonesis was noted. The corrected visual acuity was 20/200 when the patient tilted his head forward. On ophthalmoscopic examination, one noted a complete dislocation of the lens into the lower temporal vitreous chamber, and a bullous retinal detachment from above. The detachment partially obscured the optic papilla, and extended from the 10- to 2-o'clock positions, with a horseshoe-shaped tear at the 11-o'clock position, and a slight disinsertion from 12 to 1 o'clock. As the lens bounced in ocular motion, vitreous strands extending toward the detachment seemed to pull the retina farther down or allowed it to recede, depending upon the position of the lens in the vitreous chamber.

The optic disc appeared normal, and the attached retina was of usual color and appearance. The lens was spheric and small, with glistening, cholesterol-like crystals shining on its yellow-white surface. The lens usually floated in the lower part of the vitreous, where it would drop onto the retina when the patient was recumbent. With the patient prone, or when standing or sitting, it would come to the edge of the pupil leaving only enough room for him to see a little between it and the bullous detachment.

The problem this patient presented, then, was to save what little vision he had in his only remaining eye. The detachment fastened by vitreous strands to the movable lens apparently was being pulled loose by the traction between the vitreous and the lens. The pupil would not dilate to allow even this small spherical lens to migrate into the anterior chamber. There is a lack of dilator fibers present in

the iris (Dvorak-Theobald),⁷ which accounts for the fact that atropine did not affect the pupillary aperture. We were able to dilate the pupil slightly by repeated instillations of adrenalin or neosynephrin with cocaine, but neosynephrin or adrenalin alone were not effective in effecting pupillary dilation.

With the small pupil, a lens removal could not be successfully performed, for the lens could not be brought through it, therefore a preliminary iris sphincterotomy was done. The iris sphincter was cut nasally and temporally in the horizontal meridian. The sphincter was thicker than normal, and, after being cut, the pupil dilated ovally.

After sufficient time for recovery, the patient was turned face down with the foot of the bed elevated to try to get the lens into the anterior chamber. It would come to the edge of the pupil below, but not through the pupillary aperture. With track sutures, therefore, a conjunctival flap, and negative pressure by the eye speculum, the lens was brought into the anterior chamber area with a Weber loupe from the lower vitreous chamber, then grasped with a capsule forceps; the extraction was completed, and the wound closed with no appreciable loss of vitreous. The eye was softer than normal as the sutures were tied. The recovery from this part of the surgery (the lens extraction), as well as the previous preliminary sphincterotomy, was followed by a moderate striate keratitis.

As the operative reaction subsided, hemorrhage in the vitreous obscured the fundus reflex. The hemorrhage organized, while some posterior synechia developed. The endothelial surface of the cornea near the wound showed a few deep blood vessels. The eye was softer than normal. Treatment with nonspecific protein and X-ray therapy did not improve the visibility of the fundus through the vitreous

haze. The vision was limited to light perception and projection.

DISCUSSION

A diffuse pigmentation of the cornea such as was seen in this patient is of rare occurrence. The only similar instances of pigmentation of a band-shaped corneal degeneration that have been reported in the literature were those of Von der Heydt¹⁵ and Peppmueller.¹⁶ In their cases, there were no vascular nor inflammatory changes, and both occurred in patients with osteitis deformans (Paget's disease). The degeneration is of the outer layer of the cornea, hence, is epithelial. The pigmentation is located on the outside of the vesicles that are piled upon the corneal surface and diffusely invaded by blood vessels.

The cause for the pigmentation in this corneal lesion presents a most interesting problem. Klien-Moncreiff,¹⁷ in a chemical analysis of the pigment present in a corneal leucoma, found it to be hemosiderin. She believes the pigment diffused downward from the superior limbus through the intercellular spaces of the corneal epithelium.

Another theory which may obtain is that the pigment is akin to melanin. In support of this, we know from Redslob's¹⁸ studies that the basal cells of the limbal conjunctiva are all potential melanoblasts. Further, Redslob found the epithelium which covers the corneal surface to be achromogenic in normal condition; however, should a pathologic process ensue which entails vascularization, these cells become chromogenic. The query as to

where the pigment arises could be answered by Bloch's¹⁹ dopa reaction. This indicates whether a cell is a potential chromogen by its combination with 3-4 dioxyphenylalanin, or what Bloch chooses to call dopa. If the cell is a melanoblast, it is assumed to contain an oxydase ferment which, when in combination with dopa, will form a melaninlike pigment that distinguishes it as a chromogen. The blood stream is thought to be the site where dopa is carried to the cell and, when in contact with a cytoplasm of the proper type, pigment is laid down. The latter explanation would probably best fit the chromogenesis here, since the epithelial cells have undergone a cystic metaplasia wherein blood vessels freely invaded the area.

SUMMARY

A review of the literature of Marfan's syndrome emphasizes its hereditary and familial tendency. In the family reported, four of eight children were normal, whereas four manifested the syndrome, confirming its dominant hereditary trait.

The patient herein presented not only had the predominant characteristics of the disease (arachnodactyly and ectopia lentis) but also a detached retina, pulled loose by the dislocated lens. His pupil (due to a lack of dilator fibers) would not dilate with mydriatics.

A pigmented, band-shaped corneal degeneration was the unusual feature of this case, as such pigmentation of the cornea is extremely rare. A possible explanation of the origin of the pigment is postulated.

NOTES, CASES, INSTRUMENTS

PNEUMOCOCCIC CORNEAL ULCER HEALED IN 24 HOURS WITH PENICILLIN

CONSTANTIN PARAIPAN, M.D.*
Bucharest, Roumania

On March 22, 1946, Mrs. B., aged 62 years, was brought to me for examination. She was suffering from an ulcer in the left eye, which covered one fourth of the cornea, spreading from the 11- to the 3-o'clock positions. The ulcer had as an upper limit the sclero corneal limbus, and as a lower limit, a line with downward convexity near the center of the cornea.

The surface of the ulcer was irregular. It was covered with a grayish-white agglomeration and was eaten into. The edges were detached in places. Spreading in the lower-central dial from the 9- to the 6-o'clock positions and toward the center was a desquamated surface which penetrated deeply into the very tissue of the cornea. The remainder of the cornea was swollen with infiltrations.

In the lower part of the anterior chamber, there was a hypopyon $1\frac{1}{2}$ to $2\frac{1}{2}$ mm. high. The liquid in the anterior chamber was cloudy. The pupil was diminished. Chemosis and edema of the upper lid were present, as were intense perikeratic congestion, pain, tears, and photophobia. Under atropine dilatation, posterior adhesions could be detected at the 9- and 2-o'clock positions. Precipitations on the anterior crystalloid could also be seen. The eyelid remained contracted in a spasm. Vision in the left eye was diminished to the perception of hand movements.

In the inner angle of the eye, on the skin of the upper lid, and at the base of the nose, there were four groups of pus eruptions. There was folliculitis in both nostrils, as well as an ulcerated area, and thickening of the nostrils with cracks in the skin. Microscopic examination of the pus showed the presence of pneumococci.

History. In the beginning of her affection, the patient had had a suppurative infection of the nostrils. About a month before she was brought to me for examination, she began to feel prickings and pains in the diseased eye. For two weeks, the patient's eye was treated with instillations and various unguents by an ophthalmologist in Sibiu. Later, she was advised to seek treatment in Bucharest.

Treatment. After anesthetizing the eye with cocaine, I irradiated the ulcer with the platinum needle. The eye was then dressed with methylene blue of Blaché. I advised the patient's son that the only hope of saving the eye was in treatment with penicillin.

After almost unsurmountable difficulties, the son was able to purchase a phial of 100,000 units of penicillin which he brought to me on March 23rd. I started immediate treatment with sodium penicillin. Into the phial, I injected 10 cc. of a 0.75-percent sodium-chloride solution. This sodium penicillin was administered as follows: (1) 10,000 units were embodied in 4 gm. of lanolin and applied under the patient's eyelid every hour for the first day. (2) 30,000 units were injected under the bulbar conjunctiva around the cornea in six successive doses of 5,000 units every four hours. (3) 60,000 units were given intramuscularly (10,000 units every four hours, six times).

* Head of the Ophthalmological Service of the Brâncovenesc Hospital.

The conjunctival and intramuscular injections were administered at the same time. This treatment lasted for only 24 hours. For the next 24 hours, the penicillin unguent was applied to the eye every three hours.

Outcome. Three hours after the first conjunctival and intramuscular injections, the edema and chemosis of the eyelids had almost disappeared. The pustules and the nasal folliculitis had also begun to clear. Six hours after the first injection, the ulcer began to recede. The marginal zone around the ulcer (approximately 1 mm. wide) and the desquamated area no longer stained with fluorescein. The hypopyon was reduced to a trace.

After the third injection, the hypopyon disappeared completely. Spreading from the edge of the cornea like a pannus was a ramification of newly formed blood vessels. The corneal edema had disappeared, and the only posterior adherence was at the 9-o'clock position.

After the sixth injection, the ulcer was completely covered with newly formed blood vessels. The only congestion remaining in the eyeball was in the regions where the penicillin had been injected. The anterior chamber was clear, and the precipitants from the crystalloid had almost disappeared. Vision in this eye was now $1/6$. An infiltration zone remained at the 9-o'clock position but, according to the patient, this was an old spot. She said that she could now see as well as she ever had with this eye. All the pain was gone, and there was no longer any edema of the lids.

At the end of 48 hours, I observed that the congestion of the eyeball continued to reduce and that everything was progressing toward normalcy. The ulcer was still covered with a network of newly formed blood vessels which had begun

to retreat from the edge, leaving the cornea quite transparent.

Conclusions. The healing of a serious case of ulcer of the cornea in a 62-year-old woman—an ulcer which was approaching the abscess stage—was accomplished in 24 hours. The success of the penicillin treatment in this case is very impressive.

My first information on the treatment of such cases with penicillin was obtained through the American Library in Bucharest and especially from articles published in the *Ophthalmology Newsletter*.¹⁻³

In La Rocca's article,³ the quantities of penicillin used were about one tenth the amounts administered in this case. I was prompted to increase the doses because of the uncertainty of the effectiveness of the substance used. Although the label on the phial said that the penicillin was good to June 26, 1946, it also said that it should be kept at a temperature not exceeding 10°C. Since the penicillin had undoubtedly been handled by a number of black-market operators, one could be certain that this recommendation had not been observed. That is the first reason why the dosage was increased 10 times.

The second reason for the increase was to prevent the microbes from accommodating themselves to small quantities of the penicillin.

This communication is an attempt to aid in perfecting the treatment of ocular infections. The rapidity of cure in this case by administering penicillin in the very center of the infection indicates that the method is effective. Unfortunately, the lack of penicillin and its high price in our country make its use in ocular therapy an unusual event.

PENICILLIN TREATMENT OF EYELID INFECTIONS

CARL A. NOE, LIEUT. COL. (M.C.),
A.U.S.*

Cedar Rapids, Iowa

Numerous articles have appeared in the literature during the past two years relating the results of treatment of infections of the eyelids, conjunctiva, and cornea with penicillin. For the most part, these results have been very favorable, and many cures have been reported. Especially favorable results were reported by Florey, McFarlan, and Mann,¹ who treated 48 cases of marginal blepharitis, 39 of which showed staphylococcus aureus on culture, by the application of penicillin ointment containing 600 to 800 units per gm. to the lid margins, three times a day. In all except one case, symptoms were alleviated, and 36 cases showed clinical recovery after three to six weeks of treatment and one year of observation. Bellows² reported excellent results with penicillin drops and ointment treatment of acute and chronic staphylococcal conjunctivitis. Stein³ reported excellent results in blepharitis with penicillin ointment.

Unfavorable results have also been reported in the literature. Several authors (Vorisek and Evans,⁴ Selinger,⁵ Schultz,⁶

Pyle and Rattner,⁷ Bellows⁸) have reported allergic reactions to penicillin used locally in the eyes.

Since November, 1944, 55 cases of acute and chronic eyelid and conjunctival infections have been treated by us with penicillin used locally in the form of drops, 2,500 units per cc. in normal saline solution, as well as in the form of ointment, 1,000 units per gm. The ointment was prepared by dissolving the penicillin in a small amount of distilled water and mixing it with amber petrolatum. Wool fat or similar substances were not used. The cases in which conjunctivitis was the principal finding were treated by drops; those having a blepharitis, mainly by ointment; and those showing a blepharoconjunctivitis, by a combination of ointment and drops. The drops were used every hour during the day and also once or twice during the night. The ointment was used on the lid margins, three times a day. Several cases of acute meibomitis received, in addition to the application of ointment, hot compresses for 20 minutes, 3 times a day. The periods of observation varied from a week to 18 months.

The cases were classified as follows:

	Cases
Blepharitis, chronic	3
Conjunctivitis, chronic	17
Conjunctivitis, acute	10
Blepharitis and conjunctivitis	19
Meibomitis, acute	6

* E.E.N.T. Section, Surgical Service, Army and Navy General Hospital, Hot Springs, Arkansas.

Cultures on blood-agar plates were made in all cases except those in the acute meibomitis group. In the blepharitis cases, the cultures were taken from the lid margins just behind the lash line, after expression of the meibomian glands. In the conjunctivitis cases, cultures were taken from the lower palpebral conjunctiva.

RESULTS OF TREATMENT

Blepharitis cases. Of the three cases in this group, two with negative cultures developed marked dermatitis of the lids after treatment for five days and were unimproved. One case with a pure culture of hemolytic Staph. aureus was markedly improved after four weeks.

Chronic conjunctivitis cases. Eight of the 17 cases in this group were cured within one week. Of these eight patients, three had negative cultures; one showed nonhemolytic Staph. aureus; three showed hemolytic Staph. aureus; and one showed Strep. viridans.

Three of the patients were well in two weeks. Two of these showed hemolytic Staph. aureus; the culture of the other was negative. Four cases were improved after two weeks. Two of these showed hemolytic Staph. aureus, and two, negative cultures. Two were unimproved. One of these showed nonhemolytic Staph. aureus and one Strep. viridans.

Acute conjunctivitis cases. Six of the 10 patients in this group were well in one week. Four of these had negative cultures; one showed both hemolytic and nonhemolytic staphylococci, and one showed hemolytic staphylococci. One developed lid dermatitis.

Two patients, both of whom showed negative cultures, were well in two weeks. One was improved after two weeks; his culture was negative, but lid dermatitis occurred. In one case, there was no improvement after three weeks. The culture

showed hemolytic Staph. aureus. This case also developed a lid dermatitis which disappeared after penicillin was discontinued.

Recurrent blepharitis and conjunctivitis cases. Of the 14 cases in this group, three were well in two weeks. The cultures showed hemolytic Staph. aureus in one case and were negative in two. Four cases were improved in one week. Three of these showed hemolytic Staph. aureus. All four recurred later and were again improved by penicillin treatment.

Five cases were improved in two weeks. Two of these showed mixed cultures of hemolytic and nonhemolytic Staph. aureus; one showed nonhemolytic Staph. aureus; one showed hemolytic Staph. aureus; and the culture of one showed no growth.

Two cases were unimproved. One showed a mixed culture of hemolytic and nonhemolytic staphylococci; in the other, the culture showed no growth. Both of these patients developed a lid dermatitis while under treatment.

Chronic blepharitis and conjunctivitis cases. There were five cases in this group, two of which were cured in one week. The cultures showed hemolytic Staph. aureus. Two others were improved in two weeks. One of these showed hemolytic Staph. aureus, and the other nonhemolytic Staph. albus.

One case was unimproved after four weeks. The culture showed hemolytic Staph. aureus. Lid dermatitis developed.

Acute meibomitis cases. Four of the six patients in this group were cured in one week. One of these developed a lid dermatitis several days after treatment was discontinued. Two were improved in two weeks, but the usual chalazion remained.

COMMENT

Nine of the 55 cases treated developed

* Each asterisk equals one case of lid dermatitis.

allergic dermatitis of the lids. This is a higher incidence than is shown in ordinary drug sensitivity. Since normal saline solution and amber petrolatum were used as vehicles, the penicillin must have been the allergin. All cases of dermatitis recovered when penicillin treatment was stopped.

The cultures in these cases showed only staphylococci and streptococci. There were no pneumococci or influenza bacilli reported, although cultures were taken on blood agar. This suggests the possibility of laboratory errors.

The cured cases were in a mixed group, as far as cultures were concerned. Some showed negative cultures, and several of those showing hemolytic *Staph. aureus*

were not cured. Spontaneous cures must be considered.

Herpetic keratitis developed in two cases during penicillin therapy.

SUMMARY AND CONCLUSIONS

The results of treatment of 55 cases of conjunctival and eyelid infections with penicillin were tabulated.

Allergic dermatitis was noted in 16 percent of the cases.

The results for the group as a whole were not superior to those shown by other forms of therapy. In a few individual cases, however, the results were remarkable.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

April 1, 1946

DR. MAURICE L. WIESELTHIER, *presiding*

This meeting, the annual round-table discussion, was devoted to a single subject, "Complications of Ocular Surgery." Questions submitted before the meeting were edited and divided among the following ophthalmologists who comprised the panel of experts: Dr. Conrad Berens, Dr. Paul A. Chandler, Dr. John H. Dunnington, and Dr. Daniel B. Kirby. The interrogator was Dr. Isadore Givner.

PROPHYLAXIS AND THERAPEUSIS OF WOUND INFECTION

DR. CONRAD BERENS. The postoperative cataract wound may be infected from the air, conjunctiva, instruments, hands, or upper respiratory tract of the surgeon, assistants, and observers. The use of 1-percent silver nitrate preoperatively showed, in a study of 1,000 cataract extractions, suppuration in only one case. It is probably too early to say whether penicillin or sulfathiazole ointments are more efficacious than silver nitrate instilled two hours preoperatively, plus 25-percent argyrol at operation.

Conjunctival smears and cultures are taken a week before operation and, if pathogens are found, appropriate treatment is instituted. Lacrimal-sac infection should be treated, or dacryocystectomy or dacryocystorhinostomy performed. If infection persists, the puncta should be obliterated before operating. When bacteria are present in the eye and nose, they are often of the same type and toxicity. Nasal

and nasopharyngeal cultures have indicated unsuspected sinusitis. The conjunctiva may be secondarily infected from the nose and sinuses.

The surgeon and others in the operating room wear masks covering the nose and mouth. Thin rubber gloves minimize infection from the surgeon's hands. A narrow, complete conjunctival flap, carefully sutured, is most important in preventing infection. Instruments are preferably dry sterilized. Some surgeons immerse them in boiling water before introduction into the anterior chamber. A further precaution is to place instruments, sutures, and certain dressings in a 1:3,000 aqueous solution of zephiran.

Penicillin and sulfa drugs pre- and postoperatively seem to prevent certain low-grade postoperative infections, and the benefits resulting from their use as prophylactics outweigh their disadvantages.

If the anterior chamber becomes infected, wash it out immediately with penicillin. Administer penicillin intravenously in addition to appropriate sulfonamide and foreign-protein therapy. Penicillin should also be applied in conjunctival packs and by iontophoresis. Inject penicillin into the vitreous if it becomes infected by pneumococci or staphylococci. If a coliform organism is the offender, streptomycin is injected intramuscularly and perhaps locally.

TREATMENT OF EARLY POSTOPERATIVE INTRAOCULAR INFECTION

DR. JOHN H. DUNNINGTON. Most postoperative infections are due to staphylococcus aureus. Very little of any antibiotic agent applied locally, either in solution or ointment, penetrates into the

cornea and practically none into the aqueous. For effective penicillin treatment more energetic methods must be employed: (1) The eyecup, described by Struble and Bellows, through which solution can be introduced, should be applied for 30 minutes four times a day. (2) A cotton pledget saturated with penicillin (10,000 units per c.c.) should be placed in the cul-de-sac for an hour. (3) Subconjunctival injections of penicillin (2,500 units per c.c.) in novocaine or following novocaine injection give some bacteriostatic action to the aqueous. (4) Iontophoretic application of penicillin (2,500 units per c.c.) for two minutes gives the highest aqueous concentration of any of these methods. Usually 20,000 units of penicillin is also given systematically every three hours, combined with sulfadiazine, although very little of this penetrates into the ocular structures. Foreign-protein therapy probably enhances the effect of these treatments. Dr. Dunnington prefers these methods to direct injection into the anterior chamber. Vitreous injections, reserved for definite posterior infections, are not classified as early infection.

VITREOUS PRESENTATION OR LOSS IN CATARACT EXTRACTION

DR. DANIEL B. KIRBY. Presumably all precautions have been taken to avoid this complication. The loss of fluid vitreous offers less of a technical problem than normal or viscid vitreous because the eye will heal more gracefully if the cataract is extracted in capsule without undue trauma. Extracapsular extraction is difficult because the hypotony renders pressure ineffective and contraindicated because these eyes react badly to cortical remnants. Intracapsular extraction is feasible by traction, rotation, and if need be, stripping of the zonule. Accurate closure with appositional corneoscleral

sutures is important. A bubble of air or saline may replace some of the intraocular fluid.

Viscid or normal gel vitreous is more important and dangerous. If the vitreous is in the anterior chamber or in front of the lens, loop extraction is indicated because the vitreous interferes with placement of the forceps or suction cup. Place the loop carefully behind the lens to minimize vitreous loss and prevent dislodging the lens into the vitreous by other manipulation. If the vitreous is alongside the lens, forceps or suction cup may be employed. A wide iridectomy lessens the usual drawing up of the iris.

Prolapse or loss of viscid vitreous after the extraction is less serious when the intracapsular, rather than the extracapsular, method is used. Pressure is removed and the eye closed for several minutes; then cut away protruding vitreous and close accurately with corneoscleral sutures. If an iridectomy is possible and has not yet been done, do it, reposit the pillars, inject air or saline, and raise the head to help prevent iris incarceration. This careful toilet may salvage the eye; whereas, hurried backing out invites infection and poor healing with other complications.

TREATMENT FOR A FLAT ANTERIOR CHAMBER WITH SEPARATION OF THE CHOROID

DR. PAUL A. CHANDLER. Since corneoscleral sutures have been used, this has been a rare complication after cataract extraction. If it occurs and the anterior chamber is flat for an extended period, there is potential danger from peripheral anterior synechiae and glaucoma. Therefore, watchful waiting should not be employed too long, and interference is probably advisable during the second postoperative week. In two cases, the anterior chamber had been filled with air through a small puncture over the iris. When the

air was absorbed, the anterior chamber remained formed and the separated choroid had disappeared. This discussion applies, of course, only to cases without an obvious leak.

Selection of the filtration operation will to some extent avoid flat chamber. In older patients with a very thin, friable conjunctiva, there is greater likelihood of the anterior chamber remaining flat after a trephining operation than after iris inclusion. Dr. Chandler has not seen this complication persist more than a week after iris inclusion. It is safe to permit the anterior chamber to remain flat for a long period after trephination if there is free filtration. If filtration becomes less or disappears, the anterior chamber should not be permitted to remain flat too long. He has interfered in only two of these cases. In one, after a month, a sclerotomy over the separated choroid was performed with a cataract knife. The anterior chamber formed while the patient was on the operating table and in 3 to 4 days the choroid was back in place. In the other, after a similar sclerotomy, the anterior chamber was formed at once, but the choroid did not go back. If there is not free filtration, Dr. Chandler is inclined to do such a sclerotomy early, for it is safe and simple.

ATTEMPTED INTRACAPSULAR EXTRACTION THROUGH A ROUND PUPIL WHEN THE CAPSULE RUPTURES

DR. DANIEL B. KIRBY. The fragility of the capsule varies. If the forceps slip off without rupturing it, the area of application has been weakened and the next grasp should be elsewhere. A small tear can be straddled with the forceps. In larger tears above, Dr. Kirby has applied the forceps near the lower pole, tumbling the lens out in capsule. He has also slipped a second pair of intracapsular forceps held in the right hand over the torn edge

of the capsule and, with alternate traction on both forceps, removed the capsule and its contents.

If the capsule edges are not easily visible with the loupe and if the lens is less than half out, use toothed forceps, remove a large piece of capsule and perform a capsulotomy extraction.

It may be possible and desirable to remove the loose capsule after the cortex and nucleus are out. The capsule may be grasped with intracapsular forceps, drawn out a little, grasped below with other forceps, and so be gradually removed even when sufficiently fragile so that one forceps used alone would tear it. In some cases with relaxed vitreous, it is justifiable to lift the corneal flap and pick up the loose capsule.

If the posterior capsule is intact, it is feasible to irrigate away loose cortex. After all the capsule has been removed, the conservative closure of such eyes without risky manipulation is justified in order to prevent injury to the hyaloid and vitreous prolapse. Complete iridectomy depends on whether the lens cortex and nucleus are easily delivered without a coloboma. Postoperatively a round pupil is the more desirable, but the reaction of the eye may be less with an iridectomy.

IRIS PROLAPSE AND ITS TREATMENT AFTER CATARACT EXTRACTION

DR. JOHN H. DUNNINGTON. The incidence of this complication is reduced by careful wound closure. If it occurs, the general rule should be prompt excision. If more than 12 hours elapse after its appearance, a freeing of the iris is difficult. Dr. Dunnington has not had success with replacing the iris without excision, nor have such cauterizing agents as trichloracetic acid been successful. The only condition in which a decision between noninterference and excision may be difficult is when there is a small pro-

lapse completely covered by conjunctiva. He believes these should be excised as they have a tendency to enlarge. If the patient is too tense or the eye too tender for local anesthesia, pentothal sodium is very satisfactory. There is no material difference in the management regardless of the time of its appearance.

COMPLICATIONS ATTRIBUTABLE TO KEEPING PATIENTS ABED POSTOPERATIVELY

DR. CONRAD BERENS. Two patients developed hypostatic pneumonia after cataract extraction, probably the result of a long stay in bed. Severe constipation and gastro-intestinal disturbances have been common, but they can usually be controlled by colonic therapy if the usual methods for relief fail. Long bed rest with both eyes covered induces severe psychic disturbances in some patients. Nervous patients should have the unoperated eye opened the day of the cataract extraction and in 2 or 3 days following operations for detachment of the retina. The patient is propped up 30 degrees as soon as possible after operation for cataract, glaucoma, and detachment of the retina if the detachment is below. If the detachment is above, the patient is kept flat. If the cataract wound is sutured sufficiently well, Dr. Berens has permitted patients out of bed the same day, although the sedation and nerve shock make it preferable to wait until the next day. Only detachment patients are not permitted out of bed on the same or first postoperative day. They are usually kept in bed for two weeks, although certain experiences have made him question this practice. The first patient he operated on in 1930 after returning from Gonin's clinic sat up in a chair after five days because the operation seemed a failure, but later there was a complete reattachment. Two of his most unruly and restless patients have had satisfactory results.

OPERATION FOR CHRONIC SIMPLE GLAUCOMA COMPLICATED BY CATARACT

DR. PAUL A. CHANDLER. One must decide in each case whether the cataract or the glaucoma is primary. If the glaucoma is serious and the cataract not advanced, the operation is chosen on the same basis as if there was no cataract. In patients past the middle sixties, the glaucoma is very often secondary to cataract, particularly if the anterior chamber is shallow. If the cataract is nearly mature to hypermature and if the tension can be brought to reasonable limits with miotics, Dr. Chandler prefers intracapsular extraction with a broad basal iridectomy. He hesitates to do a glaucoma operation to be followed shortly after by lens extraction in these cases. The lens can be extracted successfully, but occasionally, despite careful placement of the cataract section so as not to disturb the filtering scar, it will cease to function after cataract operation.

LENS SUBLUXATION OR DISLOCATION INTO THE VITREOUS AFTER A CATARACT INCISION

DR. DANIEL B. KIRBY. A distinction must be made between cases with fluid and viscid vitreous. If preliminary examination discloses subluxation and fluid or semifluid vitreous when the section is made, the vitreous will seep away and the lens will sink. It is safe to place sclerocorneal sutures after the section. Outside pressure is ineffective, and the lens should be removed by traction with forceps. When the lens subluxates upward, Dr. Kirby recommends passing a loop down over the face of the lens and rotating it in its long axis through the break in the zonule to come up under the lens. The loop supports the lens while intracapsular forceps are placed on the capsule to draw the lens down and hold it while the loop is maneuvered to strip off the remaining zonule if necessary. The typical passage

of the loop through the upper intact zonule would risk luxation of the lens into the fluid vitreous.

If, before or during the operation, the lens is found luxated completely into fluid vitreous, then Verhoeff's technique of irrigation of the vitreous chamber, floating the lens to lift it out with a loop, appears useful. A lens adherent to the retina or ciliary body is best left alone as the eye will better tolerate the condition than the interference. Try coaxing the lens through a dilated pupil by the prone position, and then imprison it with a miotic for immediate removal.

With viscid vitreous, use preplaced sutures. If the intraocular pressure is increased, posterior drainage of the vitreous to relieve the pressure may give fewer complications than uncontrolled loss of vitreous anteriorly. A complete iridectomy minimizes updrawing of the pupil. After the aqueous escapes, the vitreous comes forward and brings the lens forward with it. The loop is passed through the zonular hiatus and a trial of traction alone is made. Pressure on the cornea is seldom necessary. Forceps support the lens while the loop strips off the zonule, sweeping around the equator where the zonule is adherent. In some cases, forceps cannot be placed on the capsule because of overlying vitreous.

A lens luxated into viscid vitreous is best visualized with ultraviolet light and its mobility tested by moving the patient. The interference and resistance of the vitreous makes it unlikely that it can be brought into the anterior chamber. If the lens remains in the viscid vitreous, it will cause degeneration and fluidification and its removal is simpler, although the prognosis is grave.

DELAYED RESTORATION OF THE ANTERIOR CHAMBER

DR. JOHN H. DUNNINGTON. Prophylactic treatment of delayed restoration of

the anterior chamber consists of accurate wound closure plus careful wound toilet. In round pupil extraction, the iris may be a causing factor, and eserine may possibly be a help as a postoperative measure. The corneoscleral suture is valuable if properly applied, but otherwise it is worse than none. The introduction of air after cataract extraction has lessened the incidence of this complication. Absence of the anterior chamber means a leaking wound calling for location and closure of the leak. A conjunctival flap generally is insufficient to close the wound. In addition, place a suture through the lips of the opening to approximate the edges. Any epithelium about the opening should be cauterized before placing the sutures.

Complications following delayed restoration of the anterior chamber are: (1) detachment of the choroid; (2) total or partial peripheral synechia; (3) adherence of the iris to the face of the vitreous; (4) there may develop adhesion between vitreous and cornea producing deep corneal opacity; (5) if the delayed restoration has followed a glaucoma operation, cataract may follow; (6) formation of a vascular membrane on the posterior surface of the cornea; (7) epithelialization of the anterior chamber; (8) glaucoma.

HYPOTONY AFTER A FILTERING OPERATION

DR. PAUL A. CHANDLER. Two points especially have a bearing: (1) A very thin conjunctiva. (2) The absence of postoperative inflammation. If, at operation, manipulation of the conjunctiva shows it is thick and strong, hypotony will seldom develop. With a very thin and delicate conjunctiva, and this is especially true of older people, it is easy to get filtration; and if a 2-mm. trephining operation is done, a soft eye will often follow. Therefore, iris inclusion, rather than trephination, is the operation of choice in older individuals with thin conjunctivas. The softest eyes are those which remain white

and quiet postoperatively. If the postoperative reaction of an eye could be predicted, one would perform an operation giving freer filtration, such as a trephination, where a stormy convalescence is anticipated; and a less extensive procedure, as iris inclusion, for little postoperative reaction. If during preparation for operation and the operation itself, the eye becomes more or less congested, one would expect a greater postoperative reaction and vice versa, but Dr. Chandler is not sure whether this is a reliable test.

For obvious leakage of the bleb, a conjunctival flap is drawn down over the opening after cauterizing the cornea around the bleb. Cauterization of the surface of the bleb may have no effect in some cases; while in other cases, if more extensive, may entirely stop filtration. Where there is no obvious leak, Dr. Chandler uses only a mild antiseptic to ward off infection. In younger patients with very soft eyes after filtering operations, one is at least sure the glaucoma is arrested. Often, after a year or two, the tension rises to reasonable levels. Post-hypotony cataract can be removed with less likelihood of recurrence of the glaucoma than if the filtration were barely adequate before extraction of the lens.

REOPERATION AFTER AN UNSUCCESSFUL OR INADEQUATE MUSCLE OPERATION

DR. CONRAD BERENS. This depends upon the type of operation and what it was designed to correct, the patient's age and health, and many other conditions. Specifically, if a patient has had an operation upon one lateral rectus in exotropia at 6 meters with little convergence insufficiency, he may have an operation within a month on the other eye for residual exotropia of 10 degrees or more. In divergence insufficiency with a resection of one lateral rectus muscle, resect the other lateral rectus after a month. If both lateral recti had been operated

upon, wait four months before reoperating. In convergence insufficiency after operating on one medial rectus, should there be a high residual deviation at the near point, do not hesitate to operate within two months on the other medial rectus unless the patient responds unusually well to convergence exercises. However, in convergence insufficiency any indicated general treatment and converging exercises should be given a thorough trial before operation. In convergence excess, especially in young children, wait three or four months after a recession on one medial rectus before operating on the other medial rectus. If both medial recti had been operated upon, wait six months before operating. In hypertropia due to weakness of one superior rectus with overaction of the inferior oblique of the other eye, if a marked hypertropia persists despite an operation on the inferior oblique, after two months consider resecting the weak superior rectus. If the patient fixes with the eye with the paretic superior rectus, vertical deviations caused by spasm of an inferior oblique tend to increase. If the vertical deviation is not stabilized, consider myotomy at the orbital insertion. Secondary cicatricial divergent strabismus after retroplacement or recession of a medial rectus is corrected by resection, advancement, and Tenon's capsule transplantation of the involved muscle after at least three months.

CHOROIDAL DETACHMENT AFTER INTRA-OCULAR SURGERY

DR. CONRAD BERENS. Detachments of the choroid following cataract extraction may occur at or immediately after operation. Dr. Berens has never operated for this type of detachment which O'Brien says occurs after practically every cataract extraction. An almost complete choroidal detachment after a glaucoma operation subsided rapidly leaving no observable ophthalmoscopic signs. If the wound heals

completely or filtration diminishes rapidly, the detachment usually heals spontaneously and requires no special treatment. These patients are permitted to be up as soon as any cataract patient. With postoperative detachment persisting longer than six weeks, consider an electrolysis puncture or a simple scleral puncture. Delayed detachments occurring months or years later may be caused by reopening of the wound or possibly by lowered intraocular pressure from other causes.

When a filtering wound has leaked as shown by fluorescein and application of trichloroacetic acid has not proved effective, Tenon's capsule has been successfully transplanted under the conjunctiva.

HANDLING OF EXPULSIVE HEMORRHAGE

DR. DANIEL B. KIRBY. Know the patient's cardio-vascular system before operation. If the systolic pressure is high, sedation and rest in bed preliminary to operation are good. If the patient is plethoric, venesection may help. If the diastolic pressure is 120 mm. Hg., there is apt to be turgescence of the choroid, presentation of vitreous, if not intraocular hemorrhage and expulsive hemorrhage. The whole mechanism also depends on how the blood vessels withstand the blood pressure and the lowering of the intraocular pressure by the incision.

Inject crude liver if the red blood cells are not normal; inject ascorbic acid, in addition to prescribing fruit juice by mouth, for its effect on the blood vessels. The patients need milk or calcium. The bleeding and coagulation time does not indicate the degree of bleeding at the time of surgery. Inject vitamin K for abnormal platelet count or prothrombin time, using care in elderly patients who may develop a thrombosis, if the action is too great, and in the patient predisposed to thrombosis.

It is best to postpone surgery for serious orbital hemorrhage after retrobulbar

injection. If expulsive hemorrhage occurs once the section has been made, put on pressure and trust the hemorrhage will stop. All one can do is to explain the situation and advise enucleation as soon as feasible.

POSTOPERATIVE HYPHEMIA AND INTRA-OCULAR HEMORRHAGE

DR. JOHN H. DUNNINGTON. Treatment for postoperative hyphemia is simple: bed rest, eye rest, watchful waiting, and no heat. If the tension is increased or the anterior chamber is filled with black blood showing no tendency to absorb, a paracentesis for removal of the blood clot is in order.

Proper placing of the incision is most important in controlling intraocular hemorrhage. A deep section is the usual cause of blood filling the anterior chamber. Should such an occurrence take place, wait until bleeding is stopped, remove the clot, and then proceed with the extraction. In a patient with high ocular tension, try to avoid sudden reduction of pressure by retrobulbar injection. If tension remains high, reduce it by very slow evacuation of the anterior chamber. Arterial tension does not seem to have anything to do with hemorrhage at the time of operation. If the iris is vascularized and the cataract is complicated, select the site of the iridectomy carefully to avoid blood vessels. If bleeding occurs at time of operation, wait until a clot forms before performing the extraction.

REOPERATION IN ACUTE AND CHRONIC SIMPLE GLAUCOMA

DR. PAUL A. CHANDLER. One may rarely see a case in which, a few hours after operation for acute glaucoma, the tension rises to an exceedingly high level, and something has to be done immediately. If operation for acute glaucoma fails to bring the tension to normal, there is usually no great urgency in doing the

second operation. It is best to wait until the eye becomes quiet or shows no further tendency toward becoming quiet. If the pressure is 30 to 39 mm. Hg., continue with miotics. Unless the field is exceptionally small or the tension is so high as to constitute a real danger, one can safely wait weeks before reoperating. If the tension is over 40 mm. Hg., one dare not wait long, as damage takes place more rapidly at these levels. In chronic simple glaucoma, follow somewhat the same rule. A guide is whether the patient can afford to sacrifice a little more vision and field while waiting for optimum conditions for reoperation. Chances for success in a second operation are better with a quiet eye, but if congestion persists there is no point in further delay.

Many of the reasons for failure of glaucoma operations are unknown, but one reason lies in the choice of operation. Iridectomy will not be sufficient in neglected primary acute glaucoma which does not respond to miotics. A filtering operation is required for this. Failures in chronic simple glaucoma may be due to errors in technique. In a trephining operation, if the trephine is slanted too much and less than two thirds of the corneoscleral button is loose when the anterior chamber is entered, it is difficult to remove the whole button with scissors. Once the trephine is applied accurately it should not be removed until it enters the anterior chamber. One may occasionally push the button into the anterior chamber, but no harm is done. A dull trephine blade adds greatly to the difficulties. In iris inclusion operations, a cause of failure is too much manipulation of the iris. The grasp of the iris must be gentle and not too wide, withdrawal should be very slow, and undue traction should be avoided. The cut should be made with very sharp scissors. Once the cuts are made, release the iris forceps immediately, and the operation is over.

Even though the iris is rolled up make no further manipulations. One of the greatest reasons for failure in all glaucoma operations, no matter how well executed, is marked postoperative inflammation. An eye remaining irritable with postoperative iritis for many weeks is very apt not to show good filtration. This is a real traumatic iritis. If a second operation is performed, everything possible should be done to eliminate foci of infection which might be factors in causing the iritis.

GLAUCOMA FOLLOWING CATARACT EXTRACTION

DR. CONRAD BERENS. If the glaucoma is caused by delayed reformation of the anterior chamber, it is justifiable to inject saline or air in an attempt to open the closure which causes difficulty. If the hypertension is caused by inflammation, Dr. Berens often injects typhoid-H. antigen intravenously, followed in 48 hours by aspiration of the anterior chamber. He frequently uses mild mydriatics and applies heat. Foci of infection are removed or resistance to them raised by vaccine therapy combined with penicillin, the sulfonamides, or other appropriate measures. If the hypertension is not marked or painful, he often aspirates. One patient's anterior chamber was aspirated 16 times before the tension was stabilized. In this patient, no chronic infection or other specific cause was found. Marked pain is sometimes relieved by injecting procaine and then alcohol through the same needle into the ciliary ganglion. If aspiration, washing out soft lens matter from the anterior chamber, repeated paracentesis, and local measures do not relieve the situation, the first choice of operation is cyclodialysis. In recent years, cyclodiathermy, or cyclo-electrolysis, has given excellent results, although in three cases the procedure had to be repeated below. If these measures do not succeed, Dr.

Berens usually incarcerates one pillar by performing a sclerectomy over one pillar subconjunctivally with a punch. If this does not stabilize tension, the other pillar is incarcerated. The final measure, which has been successful in some cases, is to perform a small trephining operation below.

GLAUCOMA APPEARING AFTER CATARACT EXTRACTION

DR. PAUL A. CHANDLER. Glaucoma appearing for the first time after extracapsular or linear extraction is not uncommon in cases in which a good deal of cortex is left. No treatment is required as long as the tension stays between 30 to 35 mm. Hg. If tension is higher and there is a large amount of cortex, it is probably best to remove some of the cortex. If there is very little cortical material, or if the extraction was intracapsular, then do nothing for the glaucoma, because in these cases the tension is usually transient and harmless. Much worry about glaucoma in the immediate postoperative period after intracapsular extraction can be avoided if the tension is not measured. When, three days after intracapsular extraction, a patient showed a hazy cornea and increased tension, nothing was done, and in two days the tension was normal. In a case in which there is marked increase in tension in the immediate postoperative period, a simple paracentesis would be the most drastic measure considered. For a theoretical choroidal hemorrhage which does not break the wound open but results in an exceedingly hard eye, one might do a scleral puncture over the area of the detached choroid.

GRASPING THE LENS CAPSULE FOR AN INTRACAPSULAR EXTRACTION

DR. DANIEL B. KIRBY. Grasping the capsule below the pupillary border is well illustrated in the Knapp operation in which the zonule is ruptured by traction,

and rotation and tumbling are started before pressure is applied. If the lower zonule always ruptured easily, this would be the best place for forceps application, but experience has shown that it is probably a better procedure to apply pressure simultaneously. The lack of transparency of the collapsed cornea is not too much of a handicap in placement of the forceps. The round pupil can be well preserved by this method. However, the degree of rotation and traction and the ability to lift the lower pole of the lens are limited by the relatively narrow and shallow anterior chamber. If forceps are not introduced carefully, the corneal endothelium may be injured. Lastly, it is not necessary to tumble all cataracts to protect the vitreous which, if properly handled, does not need protection. Vitreous loss is due to factors other than the method of delivery.

Dr. Kirby grasps the capsule above because it is more easily accessible, being directly visible when the corneal flap is elevated. This method gives the surgeon better control over his grasp of the capsule. Simultaneous pressure from below tilts the lens and permits straddling of the presenting adventitious equator. The round pupil can thus be preserved. There is greater possibility of traction and rotation with appreciation of the correct position for simultaneous pressure for greatest effect. The zonule may be seen during these maneuvers and its qualities assayed. If it is too resistant, then a dehiscence may be started by touching it at the point where it is put under tension and with such a hole begun in the zonule, tearing may be continued by traction and rotation, or the remainder of the zonule may be stripped off.

REOPERATION FOR RETINAL DETACHMENT

DR. JOHN H. DUNNINGTON. If the operation is not 100 percent successful, it

is not successful. A second operation for retinal detachment generally is not done in less than 3 to 4 weeks. If ocular tension is low and retinal detachment is not progressive, it is preferable to wait longer. On the other hand, if there is detachment with a hole not closed completely at the time of the first operation, do not delay unnecessarily. Wait only 3 to 4 weeks before going ahead with the second operation. The chances of success go down with each operation, although in one case success was achieved after four previous failures. Success resulted in 3 of 9 cases operated three times. In one patient, a successful operation was performed on her only eye after five previous operations. The condition of the eye, the extent of the detachment, and the tension of the eyeball should be the factors which determine whether to reoperate, rather than the number of previous operations.

GLAUCOMA OPERATIONS FOR NEGROES

DR. CONARD BERENS. The only operation with which Dr. Berens has had extensive experience is iridocorneosclerectomy. These wounds do not filter well and hypertension often recurs, even when combined with iridencleisis. He has used cyclodiathermy successfully several times. Cyclo-electrolysis has been used once, but the time since operation has been too short to judge the results.

HYPHEMIA AFTER GLAUCOMA OPERATIONS

The head and torso are kept elevated. In the early stages, cold compresses are applied, later these are followed by hot compresses, if tension is controlled. The anterior chamber is not irrigated, and Dr. Berens has not seen serious permanent complications. If the blood extends under the conjunctiva or is under pressure, irrigation of the anterior chamber might be advisable. Nothing used preoperatively or postoperatively has seemed to aid in

preventing hyphemia. If bleeding from the sclera or episcleral blood vessels persists at the time of operation, the actual cautery or electrodesiccation is applied. This type of hyphemia is not recurrent. In this respect it differs from the hyphemia which follows cataract extraction. In both types of hyphemia, the bleeding seems to be more from the sclera than from the iris.

Leon H. Ehrlich,
Secretary.

COLORADO OPHTHALMOLOGICAL SOCIETY

April 20, 1946

DR. GEORGE STINE, *presiding*

TUMOR OF CILIARY BODY

DR. WILLIAM M. BANE presented a man, aged 38 years, in whom, during a routine refraction, a symptomless, brown-gray spherical tumor of the ciliary body was found. It measured about 5 mm. in diameter and was attached at the 4- to the 6-o'clock position. It was easily seen through the dilated pupil, and its outline was well-shown by transillumination.

OPHTHALMIC SURGERY

As part of the annual Edward Jackson Memorial Lecture, Dr. Lawrence T. Post of St. Louis delivered an address on ophthalmic surgery in which he discussed the various details of surgical techniques used in his own work at Barnes Hospital in St. Louis. In cataract extractions, a preliminary complete physical examination including X-ray studies of teeth is insisted upon. If the blood pressure is above 200, every effort is made to reduce it, even to keeping the patient hospitalized for days or weeks before surgery. Each instrument used is dipped in zephiran

authorities. Never before has the Research Study Club had such an array of teaching talent, and the full attendance at every lecture and instruction course was a tribute of appreciation to the teaching staff.

Dr. Benedict gave a masterful treatise on diseases of the orbit. Of particular interest was Dr. Benedict's discussion of X-ray therapy for various conditions causing exophthalmos. He showed slides and moving pictures of cases of exophthalmos brought about by certain nonmalignant diseases of the orbit—Mikulicz's disease, lymphosarcoma, low-grade cellulitis, and special cases of exophthalmic goiter—which had responded successfully to X-ray therapy. The early treatment of malignant exophthalmos related to thyroid-pituitary imbalance, by using X rays on the globe, was particularly new. This treatment has met with fair success if instituted during the period of infiltration, before fibrous changes set in.

Dr. Wagener discussed retinal changes in relation to systemic disease. Sclerosis of retinal vessels is more an indication of the duration of hypertensive disease than of its severity; whereas, localized spastic constrictions are, in general, indicative of the severity. Exudative lesions depend on the degree of anoxemia, with subsequent edema and degeneration, as well as on the lack of absorption of end products. Thrombosis of a branch of a vein usually indicates a mild hypertension with chronic sclerosis of the vessel, and, from the standpoint of hypertension, the prognosis is good. The prognosis for vision is more favorable if there is early recanalization of the vessel. In certain of these cases the anticoagulants are indicated, particularly if the superior temporal vessel of an only eye is involved. Hemorrhages, edema, "cotton-wool" patches, appearing in the course of hypertension, signify beginning retinal-vascular decompensation.

The picture in glomerular nephritis is one of anemia with, in addition, vascular disease as sclerosis or spasm, the anemia being a distinguishing feature. In patients who have only a slight increase in blood pressure, albuminuria, and arteriolar sclerosis, as judged by the appearance of the retinal vessels, the condition is probably one of essential hypertension and not nephritis in about 90 percent of cases. A large percentage of nephritics show no sclerosis.

Speaking of toxic pregnancy, Dr. Wagener said that there is generalized and localized spasm of the retinal vessels. If this is not rapidly corrected by sedatives, the pregnancy should be terminated to avoid the onset of sclerosis which is irreversible. If one waits until retinopathy develops, the chance of obtaining a viable baby is extremely poor, and the chance of developing marked arteriosclerosis is great.

For Eale's disease Wagener believes that bedrest is the most important part of the treatment. Discussing temporal arteritis, he stated that the vision of 50 percent of all patients with this affection eventually becomes involved. Optic neuritis and occlusion of the central retinal artery are common complications. Recurrent spasms of the central artery or of branch arterioles may be allied to Raynaud's disease. It is probable that angioid streaks in the choroid are an expression of a generalized defect of elastic tissue in the blood vessels, as well as in the skin.

In diabetic retinopathy, Wagener feels that the early stages can be stopped or reversed if a careful diabetic regimen is instituted. He has seen "cotton-wool" patches disappear in diabetics after the clearing of an infection, such as carbuncle. The serum protein may be low in diabetes, the albumin-globulin ratio altered, and the blood cholesterol high. Retinal hemorrhages are less if these ab-

normal blood findings are corrected. X-ray therapy may promote absorption of blood from the vitreous, but has no effect on the proliferation of vessels.

The retinal hemorrhages in blood dyscrasias are a result of thrombocytopenia—not of hypoprothrombinemia (vitamin-K deficiency)—plus toxic damage to the capillary endothelium and venous stasis. The hemorrhage is usually massive and dense with white centers in leukemias. Spot hemorrhages that have white centers and regular borders are more characteristic of bacterial endocarditis; and those with irregular white centers and irregular borders more characteristic of blood dyscrasias.

Dr. Meyer Wiener gave a course in applied anatomy in eye surgery, in which he correlated many of the surgical tricks he has originated with the anatomy of the part involved. The course was fascinating because of the practical application Dr. Wiener has made of what might otherwise be abstract anatomic facts. In addition, he gave a lecture on his work with rehabilitation of the blind, outlining ways and means whereby these patients may be helped to live happy and useful lives.

In discussing cataract surgery, Dr. O'Brien stressed the value of the keratome incision; the importance of marking the limbus at the 12-o'clock position before starting the operation in order to orientate the position of the globe; the value of having the assistant apply counter pressure, above, on the scleral lip of the wound, as the lens is being tumbled; and the importance of having, in so far as possible, direct visualization of the lens as it is being grasped below with the forceps. He is able to observe the lens, as it is grasped, by elevating the flap with a suture which has a knot in one end to keep it from pulling through.

Dr. O'Brien also showed excellent slides and discussed both the history and

course of various types of ocular tumors.

Dr. Pischel discussed in great detail the diagnosis and treatment of retinal detachments. He stressed not only the importance of the patient's history but also the significance of the patient having noticed sudden showers of specks before the eyes, flashes of light, and a curtain effect blotting out part of the visual field. He said that he sometimes spends many hours searching for holes and that often these can be found only with maximum dilation of the pupil and with a brilliant, narrow, ophthalmoscopic beam shone to one side of the hole, so that it stands out by retroillumination. The position of the greatest degree of detachment does not necessarily indicate the position of the hole; since fluid gravitates down, the hole may be above. He favors the idea that most holes are the result of vitreous traction on the retina. In his studies of these cases with the Koeppel contact glass and the slitlamp, he has observed detachment of the vitreous with but a single point of attachment at the site of the tear.

Pischel feels that idiopathic detachments are frequently precipitated by minor jars or blows to the body that may be forgotten until recalled after searching questions and prolonged reflection on the part of the patient. Bumping the head, sitting down hard—such falls or jolts may be the precipitating factor in producing an idiopathic detachment. Approximately 25 percent of the patients suffering such detachments develop detachment in the other eye within five years, a fact stressing the importance of treatment of the original detachment.

There is no treatment other than surgery. Pischel advises preliminary immobilization of the eyes, in a position dependent upon the region of the detachment, to allow as much settling as possible before operation. The region of the tear is treated under direct ophthalmo-

scopic observation, using Pischel pins for localization and Pischel points for semi-perforating diathermy treatment. Dr. Pischel does not use galvanic current but has no objection to its use if combined with diathermy. He obtains about 80 percent cures in all detachments seen, and, in desperate cases, he does not hesitate to resort to Lindner's scleral shortening operation.

He feels that about 10 percent of detachments have a hole in the macular area that needs treating. If there is doubt about the presence of a hole, however, it is most likely absent, and the macular region need not be treated. Only in this respect do his ideas differ from those of the late Clifford Walker, who must be given credit for having practiced (many years before they were generally appreciated) the methods which today are considered the latest and best. Appreciation of this fact does not detract from credit due Pischel, whose work has been done independently and who popularized these concepts more than did Clifford Walker.

Dr. Harrington, in his discussion of tonometry, stressed the importance of taking tensions with two weights to determine the coefficient of rigidity of the cornea, as was advocated by Friedenwald. He feels that, in secondary glaucoma, rigidity of the corneoscleral coats of the eye is increased. This would account for an apparent increase in tension, which may not be real, and might explain the frequently observed fact that secondary glaucomas withstand tension better than primary glaucomas. Dr. Harrington is working on this problem and should soon have statistics important to an evaluation of this concept.

Dr. Swan, reporting on work for which a partial grant was given by the Research Study Club, discussed the use of new drugs in the treatment of external diseases. Apparently the Koch-Weeks, in-

fluenza, Morax-Axenfeld, pyocyaneous, and tuberculosis organisms are sensitive to streptomycin. However, these organisms become drug-resistant within a matter of a few hours. It is essential, therefore, that the initial dosage be maximal. For ocular conditions, systemic administration of 1 gm. a day, in addition to local application in the form of ointment (10,000 units per cc. for skin, and 5,000 per cc. for conjunctiva, every 2 or 3 hours); is used at present. The drug should be employed only in severe infections which fail to respond to other treatment, because 10 percent of the patients receiving streptomycin systemically develop irreversible damage to the eighth nerve. The earliest that damage has occurred in Swan's experience was after use of streptomycin for 16 days. Since most eye conditions respond in less time than this, he has not encountered deafness, resulting from the treatment with streptomycin, of any eye patient. Nevertheless, it is wise to depend primarily on local use of streptomycin whenever possible.

Regarding penicillin, in Swan's experience, 11 percent of the population became hypersensitive to penicillin after prolonged use, and so he advocates using it only in acute, not in chronic, processes. Penicillin can be very effectively introduced into the eye by iontophoresis, using 4-percent methocel in distilled water as the vehicle. Swan recommends a current of 1.5 milliamps for two minutes, the negative electrode being on the eye. This has been particularly effective for pneumococcus ulcers. By this method, the anterior chamber can be irrigated with penicillin, and penicillin can be injected into the vitreous if need be.

Swan feels that in those eye cases for which sulfonamides are indicated, for example in inclusion-body blenorrhea and trachoma, a blood concentration of 3 to 5 mg. percent is sufficient, and he recom-

mends sulfamerazine (2 gm. as an initial dose, and $\frac{1}{2}$ gm. every 8 hours thereafter) to keep the blood concentration at the desired level. Sulfamerazine stays in the blood longer than sulfadiazine and penetrates the ocular tissues with more facility. Swan's experience with pyribenzamine, in controlling allergic conditions, has been favorable.

As usual, the California weather was sunny, the atmospheric radioactivity therefrom contributing to the physical well-being of the guests, while the local ophthalmologists extended hospitality and entertainment typical of Los Angeles and not available elsewhere.

S. Rodman Irvine.

WISDOM FROM THE PAST

One hundred years ago the first American edition of Lawrence's *A Treatise of the Diseases of the Eye*, edited by Isaac Hays, M.D., of the Wills's Hospital, Philadelphia, was published by Lea and Blanchard of Philadelphia. Lawrence's *Treatise* was first published in England in 1833, and a second edition appeared in 1840. It was an informative, mature study of diseases of the eye according to the knowledge of those days, and was very popular with the practitioners. It makes fascinating reading today, for it is filled with wisdom and timeless advice.

The following excerpt from the introduction by Lawrence is as timely today as it was 100 years ago and is reproduced here to express our philosophy of modern ophthalmology.

"It is hardly necessary to enlarge on the importance of the subject, or to prove formally that a knowledge of it is indispensable to medical practitioners. Everyone feels that sight is the most valuable of the senses; that it not only is, in itself, the most important inlet of knowledge, the most valuable medium of our communi-

cation with surrounding persons and objects, but also that it is essential to the full enjoyment of our other senses; to the free exercise of almost all our other faculties and endowments; so that these lose more than half their value when sight is gone. Hence blindness is one of the greatest calamities that can befall human nature, short of death; and some would perhaps prefer the termination of existence to its continuance in the solitary and dependent state, to which life is reduced by the privation of this precious sense.

"Loss of sight is the greatest misfortune even to the rich, who can alleviate it by purchasing the aid and services of others. How much more severely must it be felt by the poor, by the middle and lower classes of society, that is, by the great majority of mankind; who, being rendered incapable of labor, and having their minds uncultivated, find their existence reduced to a dreary blank, dark, solitary, and cheerless, burdensome to themselves and to those around them. Even our great poet, who might have been supposed to find every alleviation and resource that such an affliction admits of in his highly-gifted mind, and the exhaustless stores of knowledge with which it was furnished, repeatedly reverts to his blindness, and always in a tone of anguish and despondency characteristic of recent misfortune:

"Thus with the year
Seasons return; but not to me returns
Day, or the sweet approach of eve or
morn,
Or sight of vernal bloom, or summer's
rose,
Or flocks, or herds, or human face divine;
But cloud instead, and ever-during dark
Surround me from the cheerful ways of
men
Cut off, and for the book of knowledge
fair

Presented with a universal blank
Of Nature's works, to me expunged and
raised,
And wisdom at one entrance quite shut
out.'

"It often depends on the surgeon whether the patient shall retain or lose, recover or remain bereft of vision. Common external inflammation of the eye, if neglected or improperly treated, by rendering the transparent anterior portion of the organ more or less opaque, proportionally injures vision; inflammation of the iris, when unchecked, causes contraction of the pupil and effusion of lymph, which prevents the passage of light into the eye. Affection of the nervous structure, if not arrested in its beginning, terminates inevitably in diminution or loss of sight. Such distressing results have too often been promoted by modes of treatment, in favor of which the sanction of names that have enjoyed public confidence might be adduced. The success of operations for cataract, or artificial pupil, depends entirely on the knowledge, discrimination, and dexterity of the operator. The cases now alluded to are matters of daily occurrence, and make up the bulk of ophthalmic practice. The serious responsibility, which this view of the subject unfolds, will impel every conscientious practitioner to turn his anxious attention to the affections of this important organ, and to embrace all opportunities of acquiring that knowledge, which will enable him to act decisively and effectually on occasions of such momentous consequence.

"If there are any to whom the pleasure connected with the acquisition of knowledge, the satisfaction flowing from the consciousness of important duties rightly performed, and the gratitude so warmly expressed for the inestimable benefits of averting blindness or restoring sight

should not prove an incentive sufficiently powerful to the study of ophthalmic medicine and surgery, their case must be deemed desperate; unless, indeed, their minds, insensible to higher feelings and nobler motives, should obey the impulse of self-interest and fear; unless they should be affected by the prospect of disgrace and injury, which ignorance and its inseparable blunders must entail. The consequences of wrong treatment cannot be concealed here, as in the obscure affections of internal organs; the visible changes of structure are obvious to external observation, and the unfortunate individual, whose sight is injured or destroyed by unskilful treatment, serves as a lasting memorial of the incapacity and rashness to which he owes his misfortune. The study of diseases of the eye is therefore now justly regarded as an essential part of general medical education; but it is more particularly so to country practitioners, who are thrown entirely on their own resources; who cannot, as in the metropolis, and some large cities, call in the aid of superior talent and knowledge.

"Although the importance of the subject must be admitted, it may be doubted whether the ophthalmic branch ought to be separated from the rest of medicine and surgery, as it must be, to a certain extent, by devoting to it separate courses of lectures and treatises, and 'by instituting ophthalmic hospitals. The diseases of the eye, in general hospitals, are inadequate from the smallness of their number, to the purposes of practical study, particularly that of exemplifying the various operations. Thus these institutions have been inefficient in reference to this important department. As the general body of surgeons did not understand diseases of the eye, the public naturally resorted to oculists, who, seeing such cases in greater numbers, became better acquainted

with the symptoms, diagnosis, and treatment; and especially more skilful in the operative department. At the same time, the subject being imperfectly understood was neglected in the general surgical courses, in which many important affections of the eye were entirely unnoticed, and the whole inadequately explained. Thus students, who resorted to London for the completion of their professional studies, had really no means of learning this important department of the profession, which was tacitly abandoned, even by the the hospital surgeons, and turned over to the oculists. The latter, not being conversant with the principles derived from anatomy, physiology, and general pathology, attended merely to the organ, and relied almost exclusively on what is comparatively of little importance, local treatment. Hence ophthalmic surgery, being in a manner dismembered from the general science, was reduced to a very low ebb. Until within a few years, it was, in this country at least, in a state of almost total darkness.

"It thus became desirable to establish an express and distinct school for diseases of the eye; not because the principles of treatment differ from those applicable to disease in general; nor because any peculiar mode of study is required; but in order to supply a deficiency in the existing sources of professional instruction; to provide for the affections of this important organ, those means of information, which the general hospitals neither do, nor could afford, consistently with their requisite attention to their other important objects. This proceeding, which at first view seems calculated to complete and perpetuate the separation, was the only rational mode of reuniting ophthalmic practice to general surgery.

"The more thoroughly any organ has been investigated, anatomically, physiologically, and pathologically, the better

shall we be prepared to treat its diseases. In this respect the eye is advantageously circumstanced; its anatomy is well known; its physiology clearly made out. A considerable portion of the organ is external, and the transparency of the front enables us to see much of its interior. We can observe the phenomena of disease, and the effects of remedies in some of its internal structures, in such parts as are elsewhere hidden from our view. The observations thus made on the eye are applicable to the illustration of disease and treatment in other organs. Hence if the general principles of medical science throw light on ophthalmic affections, the history and progress of the latter reciprocally afford valuable data for general pathology.

"But, can the diseases of any organ be well studied alone? Can they advantageously be made the subject of detached and separate investigation and treatment? The numerous organs which make up the human body, although various in structure and office, are all intimately connected and mutually dependent. They are merely subordinate parts of one machine; and they all concur, each in its own way, in producing one general result, the life of the individual. All the leading arrangements are calculated to give a character of unity to the organization and living actions of our frame. There is a common source of nutrition for the whole body; a single centre of circulation; hence all parts are immediately dependent for their nourishment and growth, and for the materials of their various exertions, on the digestive organs and the circulating system. There is a common place of union for sensations and volitions: the nervous system associates the actions of the various organs, and combines them for the common purposes of the economy; by means of it, the various organs *co-operate* in the healthy state, and suffer together,

or *sympathize* in disease. Thus the individual organs are not independent. The causes of their natural functions, and of those deviations which constitute disease, are not to be found within themselves, but mostly in the state of the constitution, or in that of some leading system of organs. Hence, in order to understand any part of the body, we must know the whole; and this holds equally good in disease as in health. Suppose a person complains of weak sight, we shall not be able to remedy the defect if we attend to the eye only, for probably there may be no visible alteration in the organ. We must look to the state of the circulation in the head, to the condition of the digestive organs; we must inquire into the patient's habits, into his diet, into his general mode of living, as well as into the causes which may be acting on the eye. Until this analysis has been made, we cannot know the causes of disease, nor can we arrive at clear grounds of treatment. We ultimately find that the eye must be cured, not by any direct or local measures, but by those of general influence; by loss of blood, purging, change of diet, and of other habits.

"In such a system, then, of intricate connection and mutual influence, each part will be best understood by him who has the clearest notions of the general economy. Even the practical proceedings will be most judiciously conducted by those who are in the habit of treating disease generally; who do not confine their attention to the part. This confinement is prejudicial, by producing and confirming habits of partial and narrow views, by leading to neglect of mutual relations and influences, by encouraging local treatment. Exclusive attention to a small corner of the animal structure causes a confinement of mental vision, analogous to the near-sightedness which mechanics contract by constantly poring over the minute ob-

jects of their attention. All the habits of the oculist lead to a separation and insulation of the organ. The part is detached from the system, treated by washes, drops, ointments; and this inefficient trifling impedes the progress of ophthalmic surgery. We want, instead of this, general and comprehensive views, the aid of analogy and contrast; the whole field of medicine and surgery must be laid under contribution for the principles which are to guide us in learning the nature and treatment of ophthalmic disease. Professed oculists have done little for the science, either here or abroad. The only real and valuable improvements have proceeded from men of extensive anatomical knowledge and of great general insight into disease."

Derrick Vail.

OBITUARY

THEODORE LASATER TERRY (1899-1946)

Theodore Lasater Terry was born February 19, 1899, at Ennis, Texas. He died September 28, 1946, at Boston, Massachusetts. Dr. Terry's preliminary education was obtained in Texas. He received a bachelor's degree from the Southern Methodist University, and his degree of Doctor of Medicine from the University of Texas in 1922. After serving his internship at the Henry Ford Hospital, Detroit, he did postgraduate work in general pathology at the University of Texas.

During the years that followed, Dr. Terry filled these hospital and teaching appointments:

Instructor in Medicine,	
University of Texas	1925
Associate Professor, Pathology,	
University of Texas	1926

Ophthalmic Resident,
Massachusetts Eye and Ear In-
firmery1927
Assistant Pathologist,
Massachusetts Eye and Ear In-
firmery1928
Pathologist and assistant Ophthalmic
surgeon, Massachusetts Eye and
Ear Infirmary1932
Ophthalmic Surgeon,
Massachusetts Eye and Ear In-
firmery1937
Assistant Professor of Ophthalmology,
Harvard University1940-46
Acting Head, Department of Ophthal-
mology, Harvard University ..
.....During the War.

An impressive record; each forward step based on diligence, hard work, and the efficient discharge of the duties of the one before—not a record of promotion by seniority, nor through influence. Nor did he rise by pulling anyone else down. But Dr. Terry, although a hard worker, was not a plodder, he had vision and ambition.

His vision and ambition appear most clearly in his work on retrolental fibroplasia. In the first place, he perceived, what was a surprise to us, that this disease is one of the most prevalent causes of infant blindness. In the next place, he regarded it as a problem; therefore, something to be solved, and he determined to devote himself to that task. Since the task was too complicated for one man, solving this problem would involve team work; so, he proceeded to enlist co-workers and, finally, to organize a corporation, "The Foundation for Vision," with powerful financial support and broad aims and powers. His plan was to pursue all clues and attack the problem of retrolental fibroplasia not only from the viewpoint of the pathologist, but from that of the embryologist, the statistician, and the sociologist, as well. He was able to kindle

enthusiasm in others because he had in himself the divine fire.

In addition to his affiliation with the American Medical Association, Dr. Terry

THEODORE LASATER TERRY

was also a member of the American Academy of Ophthalmology and Otolaryngology, the New England Ophthalmological Society (former president), the American Board of Ophthalmology (assistant secretary), the Association for Research in Ophthalmology (a trustee), the American College of Surgeons, and the American Association for the Advancement of Science. He was also a member of Sigma Nu, Alpha Kappa Alpha, the Harvard Club, and a lieutenant in the U. S. Naval Reserve, 1925-1927. His church affiliation was Presbyterian.

In 1942, Dr. Terry was awarded the certificate of merit from the American Academy of Ophthalmology and Otolaryngology for his research in retrolental fibroplasia, the disease which he named. If giving a disease a man's name were not taboo, retrolental fibroplasia undoubtedly would be known as "Terry's disease" because he did so much to make it known.

Dr. Terry's activities in the medical societies is apparent from a survey of the papers he published (list appended), but, like our most valuable members, he contributed much more in the discussion of papers by others than appears from a list of his own publications. Special attention may be called to his series of papers on malignant melanoma and his work on conical cornea.

Dr. Terry was married in December, 1934. Helen Terry was a true helpmate. They enjoyed travelling, especially by automobile, and had driven over a large part of this country in their specially equipped car. The unique home which they were developing was on a farm 25 miles from Boston. Always they had at hand one or two books on some topic of general interest which they were reading together—a book on history, economics, religion, politics, or especially, on the scientific advances in some field other than ophthalmology. These diverse interests made Ted an interesting companion. He was always the life of the party, a good story teller with ever a timely anecdote.

Dr. Terry had suffered repeatedly from hemorrhages from gastric ulcers and had had several operations and a dozen or more blood transfusions. He finally had the radical gastrectomy and neurotomy and was no longer threatened with this recurrent disability. Hence, it was a great disappointment to have what promised to be a most active and fruitful life cut off so prematurely by a cardiac complication.

Dr. Terry was a successful clinician and teacher, but his name will be forever associated with retrolental fibroplasia. The staggering difficulties, which beset the investigation of its cause, prevention, and treatment, served only to stimulate Dr. Terry's determination to overcome them. In this he displayed the characteristics of leadership, of enthusiasm, of patience, of scientific imagination, of tolerance of the views of others, of intolerance of any but sound scientific deductions, of ability to enlist the support and coöperation of others in what was obviously too huge a task for a single investigator.

Walter B. Lancaster.

CORRESPONDENCE

MISGIVINGS AS TO THE TECHNIQUE OF CATARACT OPERATIONS

NOTE BY DR. CRISP:

Dr. Rivas Cherif, Mexico City, has written as follows with regard to certain points at which he feels he may have been somewhat misrepresented in the editorial appearing under the above title in the American Journal of Ophthalmology for December, 1946, page 1594.

DR. RIVAS CHERIF SAYS:

My paper (referred to in the editorial)

states at least a great part of the modifications or revivals of technique for extraction of senile cataract are good, useful, and advisable; but only when they are indicated. In my opinion the mistake is made in wholesale and systematic application of all the various modifications proposed by the various authors. The operator should select what seem the most useful of these proposals, omitting the less effective. It is not wrong to use innovations, but it is wrong to use a procedure, be it old or new, which is not indicated in the particular case. I am not a skeptic, but use innovations in cases in which I

believe they are indicated. I am not partial to the extracapsular method but use both methods, and I am thus in a position to compare the two. For this reason I can state positively that the postoperative reactions are comparatively less marked after extracapsular extraction. As regards the suggestion that excessive pressure may be exerted by Mexican surgeons who use the intracapsular method, I may state that in my own work I do not exert any pressure at all. Furthermore, mere tension on the fibers of the zonule is capable of causing increased ciliary reaction. As regards the question of waiting for maturity, in my opinion most patients show so much difference as to the stage of development of the cataract in the two eyes, that they are still able to use the unoperated eye after extraction of the mature cataract from the other eye. Even where the progress of the two eyes is more synchronous, there is no objection to waiting for full maturity in the second eye, and this will

imply that each of the cataracts can be operated upon at maturity.

(Signed) M. de Rivas Cherif,
Mexico, D. F.

X-RAY STUDIES IN RETINOBLASTOMA

In the January, 1947, issue of the JOURNAL, two cases of retinoblastoma are reported. It is not clear whether X-ray studies of the affected globes were made. Possibly if the technique of Pfeiffer, *Archives of Ophthalmology*, 1936, volume 15, May, pages 811-821, had been used, the finding of opaque areas of calcification might have led to an earlier diagnosis.

The procedure recommended by Dr. Pfeiffer can be employed by any careful roentgenologist, as it consists only in X raying the globe to demonstrate intraocular opacities. I recall two cases in which such X-ray studies furnished decisive information.

(Signed) Loren Guy,
New York, New York.

BOOK REVIEW

OPTIQUE INSTRUMENTALE. By G. A. Boutry. 540 pages. Paris, Masson et Cie., 1946.

It is refreshing to note that so admirable and interesting a book and one so beautifully printed can be produced in war-torn Europe. This book is based on a series of lectures to students and deals with the entire subject of instrumental optics, as distinguished from geometric optics, except computation. That subject is dealt with in a separate course. Optical principles are thoroughly elucidated without mathematics beyond the capability of an ophthalmologist. However, the oph-

thalmologist will read the book, for the most part, because the subject delights him, and not to increase his usefulness in his profession.

There are two chapters on the optics of the human eye and the corrections of the optical defects. The analysis of resolving power is discussed with particular clarity and interest. The last section of the book consists of a number of monographic chapters on individual optic instruments—lamps, the compound microscope, telescopes, binoculars, and photographic instruments.

F. H. Haessler.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

1

GENERAL METHODS OF DIAGNOSIS

Barrios, R. R., and Barriere, R. V. Regarding goniophotography. *Amer. Jour. Ophth.*, 1947, v. 30, Jan., pp. 49-51. (10 figures.)

Ferrié, Jean. The importance of questioning the patients for the diagnosis of ocular tuberculosis. *Ophthalmologica*, 1946, v. 111, June, pp. 332-338.

The author stresses the importance of the personal and family history as a diagnostic help in ocular tuberculosis. Five case histories illustrate the etiological problems of these diseases and their differential diagnosis.

Alice R. Deutsch.

Filatov, V. P., and Bushmich, D. G. Modification of Baillart's ophthalmodynamometer. *Oftal. Jour. (Odessa)*, 1946, pt. 2, pp. 7-8.

The modifications of the instrument consist in a device which locks the indicator so that it can be read after taking the instrument off the eyeball, and in the attachment of a 13-diopter lens to the stem of the ophthalmodynamom-

eter so that it can be used with indirect ophthalmoscopy. (Illustration.)
Ray K. Daily.

Guy, L. P. A ruler for measurement of visual fields on the tangent screen. *Arch. of Ophth.*, 1946, v. 36, Nov., pp. 617-619.

A rule is described by means of which one can measure angular distances on a tangent screen. The three surfaces of a triangular rod are so calibrated that one can measure fields taken at 1, 2, and 3, meters.

R. W. Danielson.

Maggiore, L. Modifications of the Schiötz tonometer. *Ann. di Ottal.*, 1946, v. 73, Feb., pp. 122-125.

The scale plate bears scales for the 5.5-gm., 7.5-gm., and 10-gm. weights in addition to the usual scale of 20 arbitrary gradations. By means of lines projected from the latter upon the other scales it is possible to read the tension directly in mm. Hg without recourse to a graph.

Not only the 5.5-gm. weight but also the 7.5-gm. and 10-gm. weights are

built into the instrument and may be brought into play, as required, by the simple turn of a lever. In this way the awkward changing of weights is avoided. Harry K. Messenger.

Pfeiffer, R. L. Roentgenography in ophthalmic diagnosis. *Arch. of Ophth.*, 1946, v. 36, Nov., pp. 639.

After listing and evaluating the uses of roentgen rays in ophthalmology, the author demonstrates and discusses recent contributions of roentgenology to the study of diseases of the eye. Deposits of calcium were found in approximately 80 percent of a large series of cases of retinoblastoma and calcium was observed microscopically in only an additional small percent. Internal fracture of the orbit was demonstrated as the cause of enophthalmos when there was no external bony deformity. Intracerebral deposits of calcium were the most important diagnostic finding in toxoplasmosis (9 cases). The value of roentgenography in the study of exophthalmos was emphasized by the fact that in 70 percent of 200 consecutive cases, changes were demonstrated roentgenologically. In 42 percent of all cases the changes were diagnostic. These diagnostic findings are illustrated by the presentation of a number of examples of each.

R. W. Danielson.

Reis, J. L. Use of "contact corneal rings" in X-ray localization of intraocular foreign bodies. *Brit. Jour. Ophth.*, 1946, v. 30, Aug., pp. 462-464.

The various methods used for X-ray localization of foreign bodies are all quite satisfactory; however they all require special equipment which, at least in war theaters, is difficult to obtain. The author describes a very thin metal ring, 0.1 mm. thick and 1.5 mm. wide,

which he cut from sheets of lead and tin alloy in which dental X-ray films are packed. He molds the ring on an artificial eye with his finger tips and places it on the cornea so that its outer edge is directly on the limbus. The strip remains in place by natural adhesion to the cornea and by pressure of the closed lids. Anteroposterior and lateral exposures are made and the usual three-dimensional measurements taken. (3 diagrams.) Morris Kaplan.

Sheppard, E. A. W., and Romejko, W. J. Gonioscopy. *Amer. Jour. Ophth.*, 1947, v. 30, Feb., pp. 159-164. (11 figures, references.)

Streiff, E. B. and Bischler, V. The precision of the ophthalmodynamometric method. *Ophthalmologica*, 1946, v. 112, July, pp. 19-24.

A thorough mathematical analysis of pertinent data demonstrates that ophthalmodynamometry is no less precise than tonometry. It should therefore take its place among the classic methods of ophthalmologic examination. (References.) F. Nelson.

2

THERAPEUTICS AND OPERATIONS

Assettati, Vincenzo. Results obtained by intravenous administration of Petragani's M.F. tuberculin in some cases of ocular tuberculosis. *Riv. di Oftalm.*, 1946, v. 1, May, pp. 292-319.

Petragani's M.F. vaccine is an extract from tubercle bacilli treated with phenol, acetone, sulfuric acid, and formol; the partigene "fenbattacin," thus obtained, is of high antigenic power, and is used in an undisclosed solution in seven concentrations. It is believed to be stable and has been used, since 1936, in pulmonary as well as extra-

pulmonary tuberculosis. Injections were given at intervals of four to twenty days in increasing concentration for three to eight months. No unfavorable reactions were observed; local and general reactions occurred but were transient only; they seemed to introduce a definite improvement in most instances. K. W. Ascher.

Azzolini, U. Severe involvement of cornea and of the skin during treatment with a goldarsenobenzol derivative. *Riv. di Oftalm.*, 1946, June, v. 1, pp. 361-373.

A 37-year-old woman developed lupus at the age of 25 years, and responded well to gold treatments, administered in two courses. After the second course, marginal infiltrations were observed in the cornea which became much worse during a third course of the goldarsenobenzol derivative. Bullous erythema developed on the face and neck, multiple deep yellowish-gray corneal infiltrations appeared and the visual acuity was reduced to the perception of hand movements. A recurrence of pleurisy, ulcerations of the mucous membranes of the larynx, severe diarrhea, and Eosinophilia accompanied the untoward reaction. Nine months later the visual acuity was 2/10 in each eye. The author discusses the allergic and idiosyncratic factors in the pathogenesis of these reactions to aurotherapy. K. W. Ascher.

Calamandrei, Giorgio. Personal experiences with penicillin treatment in ophthalmology. *Riv. di Oftalm.*, 1946, v. 1, March, pp. 180-188.

Local penicillin therapy proved to be successful in cases of conjunctival disease caused by staphylococci and by gonococci; in cases due to diplobacillus Morax-Axenfeld, zinc sulphate gave

better results. Penicillin ointments were found helpful in blepharitis if care was taken to combat the general deficiency. The results obtained in treatment of trachoma were not encouraging. Usually a solution containing 5000 Oxford units per c.c. was applied; in mild cases lower concentrations may be used. Penicillin will not displace all other drugs, particularly not those of the sulfa group. K. W. Ascher.

Carlevaro, Gianfranco. Histamin for ocular analgesia. *Riv. di Oftalm.*, 1946, v. 1, April, pp. 245-248.

Solution of bichloride of histamin administered intradermally or by iontophoresis proved to be helpful in combatting pain connected with fifth nerve neuralgia, keratoconjunctivitis scrophulosa and other types of keratitis, scleritis, iritis, iridocyclitis, glaucoma, and ocular injury. In four patients suffering from severe pain connected with herpes zoster, daily histamin administration for a week allowed discontinuation of sedatives. While no effect on intraocular pressure was observed, preoperative histamin iontophoresis proved to be beneficial in patients suffering from acute glaucoma. K. W. Ascher.

Feldman, J. B., and Abrahams, H. J. Fluorescent colors in tangent screen examinations. *Arch. of Ophth.*, 1946, v. 36, Nov., pp. 537-539.

A method is shown by which fields can be taken on the tangent screen under regular illumination and plotted with the ordinary targets now in use, but marked off by invisible fluorescent colors read under ultraviolet illumination. R. W. Danielson.

Fontana, G. Sulfonamide treatment in ocular affections. *Rassegna Ital. d'Ottal.*, 1941, v. 10, May-June, p. 253.

The literature is reviewed and the result of treatment in 200 eyes is reported. Good results were obtained in catarrhal and gonococcal conjunctivitis, phlyctenular disease, and suppurative retrobulbar infections. Unfavorable results are reported in trachoma with corneal complications and in acute dacryocystitis.

E. M. Blake.

Harris, R., McGavack, T., and Elias, H. The nature of the action of dimethylaminoethyl benzhydryl ether hydrochloride (benadryl): effects upon the human eye. *J. Lab. and Clin. Med.*, 1946, v. 31, Oct., pp. 1148-1152.

The pupillary size and visual acuity of 20 ambulatory patients, free from ocular and autonomic disease, were studied before, during, and after the use of benadryl orally in doses of 150 to 400 mgm. daily, for 3 to 12 weeks. No perceptible change was noted.

In 60 subjects, 21 to 65 years of age, fresh 0.5-percent aqueous solution of benadryl was instilled each ten seconds for three doses into the right eye. In 48 patients the pupil increased an average of 1.9 mm. at the end of one hour, and in 12 patients there was no change in the pupil size. Dilatation started to decrease in two hours and was measurable at the end of 24 hours in only four patients. The visual acuity was decreased in 12 patients and unchanged in 48, and the accommodation was decreased in 43 patients. No change was noted in pupillary size or accommodation in any left eyes at 1, 15 and 60-minute intervals.

In six patients one drop of 1/1000 epinephrin solution was instilled with the three benadryl drops, which led to maximum dilatation in 15 minutes, but the dilatation was not greater than in those who did not receive the epinephrin.

One percent solution of homatropine sulphate caused a greater increase in pupillary size in 15 subjects, when benadryl drops were added than alone. Benadryl lessens the miosis produced by eserine. Applied topically to the human eye benadryl seems similar to atropine in paralyzing the vagus. (2 tables, references.)

Bennett W. Muir.

Iliff, C. E. Beta irradiation in ophthalmology. *Trans. Amer. Acad. Ophth.*, 1946, Sept.-Oct., pp. 36-46.

Because of its limited penetration and ease of application, beta irradiation is especially suited for radiation therapy of the anterior part of the eye. A special soda-glass-windowed brass applicator containing 200 to 500 mc of radon is applied at a distance of 1 to 3 mm. from the lesion. The dosage is measured in gram seconds, 12 is the maximum for one treatment and 18 for a two-week series. After rest periods of two weeks, one or more series may be subsequently given. In 60 patients with vernal conjunctivitis 18 percent were cured, 63 percent were improved, and 7 percent were unimproved. Of 72 eyes with anterior ocular tuberculosis, vision was improved in 42 percent, maintained in 46 percent, and decreased in 12 percent. In 24 cases of benign tumor of the lids and conjunctiva, mostly angiomas and papillomas, the results were excellent. In chronic corneal affections where it is desirable to decrease vascularization the results were good.

Chas. A. Bahn.

Jona, Sergio. Investigations concerning the action of choline and some choline esters on the normal human eye. *Riv. Oto-Neuro-Oft.*, 1941, v. 18, Nov.-Dec., pp. 510-529.

Choline, acetylcholine, Doryl, mech-

olyl, and lymphogangline were used on four normal persons to study the effect of instillation into the conjunctival sac. Pupillary diameters, intraocular vascular pressure, caliber of the retinal vessels, and intraocular pressure are shown in extensive tables. In some experiments the instillation of pilocarpine, or homatropine preceded the drug to be studied. Some experiments were performed by subconjunctival administration of the solution. Instillation of choline, acetylcholine, and lymphogangline did not produce marked changes whereas doryl instillation was followed by a definite decrease of tension; subconjunctival injection of choline and of lymphogangline induced a slight fall of intraocular pressure. A decrease of the retinal arterial blood pressure and an increase of the diameter of the retinal arteries followed subconjunctival injection of lymphogangline.

K. W. Ascher.

Katzin, H. M. **Animal operating equipment for experimental ocular surgery.** *Arch. of Ophth.*, 1946, v. 36, Aug., pp. 215-219.

An operating table mounted on the elevating table of a Zeiss slit lamp is described. The swinging arm of the slit lamp is utilized to hold a microscope or camera. Illumination is provided by a hammer lamp mounted on a gooseneck. The animal, usually a rabbit, is fixed to the table by adjustable leg clamps. A circular hand rest is provided. Details of the construction and utilization of the table are given.

John C. Long.

Kuhn, H. S. **Sodium sulfacetamide 30-percent solution in ophthalmology.** *Trans. Amer. Acad. Ophth.*, 1946, May-June, pp. 210-213.

Dickson, in Scotland, found the inci-

dence of ulcers among miners after the removal of foreign bodies was markedly reduced by the use of 10 percent sodium sulfacetamide, which in England goes under the name of "Albucid."

Kuhn routinely uses a drop of the 30 percent solution every four hours for three days, after the removal of a foreign body. The ointment may be used nightly if there is conjunctivitis. Neither the drops nor ointment are irritating and no allergic reactions have occurred.

Chas. A. Bahn.

Leopold, I. H., and LaMotte, W. O., Jr. **Influence of penicillin on the course of ocular lesions due to a toxic agent.** *Amer. Jour. Ophth.*, 1947, v. 30, Jan., pp. 41-48. (6 figures, references.)

Maione, Mario. **Experimental and clinical contribution on the antiseptic action of mercurochrome in ophthalmology.** *Ann. di Ottal.*, 1946, v. 73, Feb., pp. 114-121.

Mercurochrome was introduced into Italy in 1942. Tests made in vitro with conjunctival flora show that it has greater antiseptic properties than protargol and mercury oxycyanide. Experiments made in vivo show that it can kill germs in the conjunctival sac and that it can be used advantageously in septic affections of the globe and its adnexa.

Maione proposes its administration in the form of gelatin disks so as to avoid contact with the skin. The undesirable local reactions described by others may be due to contact with the acid perspiration of the lids. Mercurochrome is precipitated in an acid medium, with the formation of irritating compounds, but is not precipitated in the alkaline medium of the conjunctival sac. With alkaloids it forms insoluble compounds, but Maione concludes that

mercurochrome and neutral atropine sulfate may be used together without any danger. Harry K. Messenger.

Marconcini, Eraldo. The action of the amide of nicotinic acid on the optic nerve of animals (rabbits) poisoned by quinine (hydrochloride). *Arch. di Ottal.*, 1946, v. 50, Jan. and Feb., pp. 19-43.

The therapeutic uses of nicotinic acid and its amide in ophthalmology are reviewed. Rabbits were given 180-240 milligrams of quinine hydrochloride intramuscularly for nine to twelve days, after which one eye was enucleated. After one day of rest the rabbits were given nicotinamide for 14 to 24 days, when the remaining eye was enucleated.

The first eye showed the usual degeneration of the myelin sheaths. The nerve of the other eye showed an almost complete regeneration of the myelin tissue and disappearance of the fatty degeneration characteristic of quinine poisoning.

The author assumes that the improved metabolism due to the vasodilating action of the nicotinamide, and the increased gaseous exchange, that is ascribed to the action of nicotinamide may explain its action on the elements of the optic nerve.

Francis P. Guida.

Moreu, Angel. Chemotherapy of ocular infections. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Sept., pp. 797-802.

The treatment advocated by Moreu consists of a massive dose of foreign protein, large oral doses of sulfa drugs, paracentesis and evacuation of the anterior chamber 24 hours after institution of treatment, and autochemotherapy every 48 hours, if necessary. In serpig-

inous ulcer a contact lens filled with the patient's blood is applied to the cornea, to bathe the cornea in blood which has a high concentration of the sulfa drug, and to stimulate the local defensive forces. These procedures invariably arrested the process in 18 cases of purulent iridocyclitis and serpiginous ulcer.

Ray K. Daily.

Payot, Pierre. The influence of anesthetics on histamine chemosis in rabbits. *Ophthalmologica*, 1946, v. 112, July, pp. 25-38.

A five-percent aqueous solution of histamine (-HCL) instilled into the eye of a rabbit produces a conjunctival chemosis after approximately five minutes. If an anesthetic, such as cocain, is applied first, the degree of chemosis is considerably reduced. This inhibition is not ascribed directly to an antihistamine action or to an affect on the nerves. The anaesthetic holocain produces chemosis by itself. (1 curve, 1 table, references.) F. Nelson.

Regoli, A. Concentration of sulfa-pyrodine in the aqueous after local application. *Rassegna Ital. d'Ottal.*, 1941, v. 10, May-June, p. 269.

Experiments on rabbits revealed a good concentration of the drug after application of ointments and instillation into the conjunctiva, and an even higher concentration after subconjunctival injection. Intraorbital injection produced very slight concentrations in the aqueous.

E. M. Blake.

Sorsby, A., and Ungar, J. Pure penicillin in ophthalmology. *Brit. Med. Jour.*, 1946, Nov. 16, pp. 723-731.

Penicillin in use up to a few months ago contained 80 to 90 percent of impurities; now most of it is up to 80 per-

cent pure and limited quantities of pure penicillin are available.

The pure substance combined with calcium or sodium is crystalline, yellowish white, freely soluble, and more stable than commercial (impure) penicillin. The dry form remains stable at room temperature for many months. Aqueous solutions, if kept sterile, remain active at room temperature for 14 days and retain potency up to four weeks if kept on ice. One milligram of pure penicillin corresponds to 1660 units.

Commercial penicillin in the usual clinical doses, used systematically, does not penetrate into the interior of the eye. Locally, in the conjunctival sac, it is not tolerated. It gives rise to hyperemia, discomfort, and sometimes to damage of corneal epithelium. Subconjunctivally, the eye tolerates from 600 to 2000 units in 0.5 mls of water.

Tolerance experiments with pure penicillin were performed on rabbits' eyes. Guinea pigs were unsatisfactory for study. Drops and ointments in concentrations up to 100,000 units per mil or gram were well tolerated in the conjunctival sac. Up to 50,000 units in 0.5 mls of water can be injected subconjunctivally, and intravitreal injections of 10,000 units in 0.2 mls can be made. Pure penicillin should be dissolved in water rather than in normal saline solution to avoid a hypertonicity. Anterior chamber infections in experimental animals were readily controlled by the use of concentrated ointment and subconjunctival and systemic injections. Aqueous therapeutic levels of the drug may be maintained by the use of concentrated ointments in the conjunctival sac but higher and more persistent levels are secured by conjunctival injections. Systemic massive doses may be adequate but evanescent. Adrenalin

in the solution used for subconjunctival injections increases persistence. Intramuscular beeswax injections give more sustained levels.

Francis M. Crage.

Souders, B. R., and Forestner, H. J. *Plastic ocular prostheses in unusual sockets.* Trans. Amer. Acad. Ophth., 1946, Sept.-Oct., pp. 46-52.

A method of socket impression and prostheses especially adapted to deformed sockets is described and illustrated with two case reports. For the impression a finely powdered alginate gel is used which sets in from two to five minutes. An impression tray of acrylic resin with a scleral radius of 12 mm. and a corneal bulge of 7.5 mm. is located slightly nasal to the center of the tray. A plaster bowl, Jaeger spatula, iris spatula, and muscle hook comprise the rest of the equipment. The technique involves the mixture, molding, impression, and trimming of the impression material, also the fabrication of the prosthesis which is made of methyl methacrylate. The iris is colored with oil pigments or a glass iris from another prostheses is used. (18 figures.)

Chas. A. Bahn.

Van Loon, J. A. *The cold pressor test in ophthalmology.* Ophthalmologica, 1946, v. 112, Aug., pp. 63-71.

The cold pressor test is a standard method for measuring the reaction of the vascular system. The blood pressure is measured at regular intervals (at first every 30 seconds, then every minute) after immersion of the hand into ice water. Normally the rise in systolic and diastolic blood pressure does not exceed 12 and 10 mm. Hg respectively. A greater rise is called a hyperreaction and is seen in hypertension. Patients with spasm of the retinal

arteries have a systolic and diastolic hyperreaction even when the blood pressure is normal. Patients with thrombosis of the central vein of the retina usually have affections of the heart and blood vessels, but react normally to the cold pressor test, except when they have coexistent hypertension. In eight patients with visual disturbances who for various reasons had increased vasomotor irritability (quinine or nicotine poisoning), a distinct hyperreaction to the cold pressure test was also found. (4 figures, 2 tables, references.) F. Nelson.

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Adrian, E. D. Rod and cone components in the electric response of the eye. *J. Physiol.*, 1946, v. 105, July 15, pp. 24-37.

The electric response of the human eye to a flash of light can be divided into a rapid component apparently associated with the photopic mechanism, most prominent with long wave-length light, and a slow component of the scotopic mechanism, most prominent with short wave-length light. Records obtained from monkeys, whose vision is nearest that of man, and pigeons, who have good colour vision and many cones, showed in each species the dual type of response. The scotopic component was smaller in pigeons than in the other two. Records from cats and rabbits, which have few cones, and guinea-pigs, in which rods predominate, gave tracings in which it was impossible to distinguish two components. The

light adapted rod mechanism of the guinea pig gave a response which resembles the photopic effect. Records were also made of the optic nerve of the cat, rabbit, and guinea pig, and from the striate area of the monkey brain, which showed little more than the apparent lack of correspondence between the electric response of the eyeball and the discharge of impulses from the retina. (17 figures, references.)

Bennett W. Muir.

Beach, S. J. Current problems of myopia. *Trans. Amer. Acad. Ophth.*, Nov.-Dec., 1945, pp. 66-70.

Groups of myopic patients were classified according to the distances at which the use of uncorrected vision caused the most discomfort. A small number of patients had discomfort at all distances; a much larger group had discomfort especially for distance; a small group had symptoms for middle distance; and an inconsistent group had symptoms especially following close work. Most of the subjects with low myopia were found in the second and fourth group. The criteria of myopia included visual acuity test, retinoscopy and refraction in cycloplegia, and near point tests.

Squeezing and retraction theories of myopia and some practical problems in the author's experience are discussed.

Chas. A. Bahn.

Chapanis, A. The dark adaptation of the color anomalous. *Am. J. Physiol.*, 1946, v. 146, Aug., pp. 689-701.

A relationship between dark adaptation and color blindness was found in recent studies of color defectives. Results of red and violet dark adaptation tests on red anomalous, violet anomalous, and normal subjects are given.

F. M. Crage.

Cotlier, I. Applications of the colored velonoscope in the study and final correction of astigmatism. *Anales Argentinos de Oft.*, 1946, v. 7, Jan.-Feb.-March, pp. 1-6.

Using the technique of Trantas, but employing a colored velonoscope, one can determine, by movement of colored shadows, whether astigmatism exists, the direction of movement of the principal meridians, and the dioptric strength of these meridians. The author's method simplifies and makes more secure the older technique of velonometry. (Bibliography, 5 illustrations.) Edward Saskin.

Dallos, J. Sattler's veil. *Brit. Jour. Ophth.*, 1946, v. 30, Oct., pp. 607-613.

Sattler's veil is the name given to the haziness that occurs in the vision of contact lens wearers as a result of corneal edema. It has been ascribed to "internal suffocation" as a result of interference with the circulation of the blood. "Outer suffocation," due to the elimination of free access of air to the cornea has also been postulated. To test this theory, Dallos drilled several tiny holes in the corneal part of his lenses near the upper part of the limbus. In two patients there was some increase of tolerance of the contact glass. The essential characteristics of an adequately fitted contact glass are discussed. Morris Kaplan.

Deloge, C. Visual reëducation in aniseikonia. *Ann. d'Ocul.*, 1946, v. 179, March, pp. 149-157.

Inequality of the retinal images of more than four degrees usually produces symptoms. Inequalities may be constitutional or acquired and include anisometropias of more than two diopeters, conical corneas, and other abnormalities which change the size or shape

of one or both retinal images. A psychic struggle results because the visual images are not blended into a harmonious three dimensional concept, but each eye struggles with the other for supremacy.

The optical treatment of anisikonia is accomplished by contact glasses and by lenses with the proper combination of thickness, curve, and index of refraction to equalize the size of the two retinal images. Prismatic glasses are of no value. The optical treatment is complicated by the fact that the size and shape of retinal images vary with the distance of the object viewed. The author believes that the Dartmouth school has secured great optical accuracy in the measurement of anisikonia but has not sufficiently emphasized the human factor in its treatment. The author examined a series of patients with anisometropia with the diploscope of Remy. Several with severe monocular amblyopia with and without high refractive errors were greatly improved by monocular occlusion of the better eye. In the second stage of treatment he strove for the production of alternating vision; and in the third for the development of simultaneous vision. During the first stages of orthoptic training slight strabismus or nystagmus may be observed. The symptoms associated with anisikonia do not exist if one eye is suppressed as in using a monocle. (References.)

Chas. A. Bahn.

Doesschate, J. T. Visual acuity and distribution of percipient elements on the retina. *Ophthalmologica*, 1946, v. 112, July, pp. 1-18.

The author presents a theoretical, largely mathematical analysis of pertinent known data. Theoretically one would expect the visual acuity to be di-

rectly proportional to the number of percipient units per unit of retina. This is true for a central area whose radius is 10 degrees. That it is not true beyond this circle is explained by assuming that in the retinal periphery percipient units consist of groups of percipient histologic elements. The total number of percipient units appears to be the same as the number of fibers in the optic nerve. (3 figures, 5 tables, references.)
F. Nelson.

Druault, A. Visual symptoms following the use of the microscope. *Ann. d'Ocul.*, v. 179. March, 1946, pp. 138-142.

In the use of monocular instruments such as the ordinary ophthalmoscope, retinoscope, and keratometer, the closure of the nondominant eye or the suppression of its visual image is necessary for those who are not ambiocular. After prolonged use of these instruments the author reports a frequent doubling of horizontal but not of vertical lines. This is attributed to a mechanical modification of the lens caused by a peculiar type of accommodation involved, and is further increased by faint transverse folds in the corneal epithelium that result from decreased winking and increased pressure of the lids. In the use of monocular optical instruments, the relationship between accommodation and convergence is disturbed. Accommodation is relaxed, but the tendency for convergence is maintained. This results in frequent homonymous diplopia of nine prism diopters or less and may be demonstrated by placing a red glass before the observing eye. The addition of a +1.50-diopter sphere to each eye may reduce symptoms. If they continue, a frosted glass may be worn before the nonobserving eye. Chas. A. Bahn.

Gardner, H. O. Obstacles in the orthoptic treatment of squint. *Jour. Iowa State Med. Soc.*, 1947, v. 37, Jan., pp. 17-21.

The most frequent causes of failure are amblyopia, suppression, abnormal retinal correspondence, vertical imbalances and poor cooperation of parents or child. The treatment of amblyopia succeeds best before the age of six years, and requires corrective lenses, and constant, complete occlusion of the fixating eye. Suppression and abnormal retinal correspondence are best treated by occlusion and stimulation on a major amblyoscope. The most common cause of failure is an uncooperative parent.
I. E. Gaynon.

Goldmann, H. A directly registering adaptometer based on a new principle. *Ophthalmologica*, 1944, v. 107, Jan.-Feb., pp. 55-59.

The author describes his mathematically exact registering adaptometer. The instrument covers a wide range of intensity of illumination (1 to 10^{-5}) and registers the data as a logarithmic graph. This instrument gives a complete and exact adaptation curve such as is desirable for purposes of research. (3 drawings, 1 picture.)

Max Hirschfelder.

Hartridge, H. Colour receptors of the human fovea. *Nature*, 1946, v. 158, July, pp. 97-98.

A retinal micro-stimulator, consisting essentially of a microscope used in reverse, which presents to the eye of the observer a greatly diminished image of a white test-light, was devised. With this it was possible to move a narrow exploring pencil of light slowly and under control over the fovea, and to test point by point the colour vision of the chosen retinal area. In some

places the light appeared red (matching light of 6,400 Å), in others green (matching light of 5,400 Å), in others blue (matching light of 4,800 Å), and between these points numerous other areas with nonspecific white or yellow response. The precise positions of these points could be measured as the distance from the test-light from the fixation light. From these data it was inferred that the Young trichromatic theory of colour vision is substantially correct, with additional yellow or white receptors, or both, that fixation can be so precise that it is possible to stimulate either single cones or very small groups of cones, and that it has been possible to identify with the precision of at least half "the cone intercentre distance" the position of some of the receptors which possess specific colour properties. Bennett W. Muir.

Holmes, W. J. Night vision. *Arch. of Ophth.*, 1946, v. 36, Aug., pp. 141-154.

Two hundred and seventeen high school students of Japanese ancestry and an equal number of Caucasian ancestry were subjected to identical tests of their day vision, night vision, and yellow and blue perception. There was no perceptible difference in the corrected day vision of the two groups. Myopia or myopic astigmatism was found in 28.11 percent of the Japanese children and in 5.07 percent of the Caucasian. Blue and yellow perception was essentially normal in each group. The Japanese as a whole did less well in all of the tests for night vision. The results obtained with the S. A. M. Night Vision Tester, with the Hecht-Shaler adaptometer and in the Harman, Ferree-Rand, and Luckiesh-Moss tests are analyzed. Various theories are stated to account for the definite difference in night

visual acuity in the two groups. These include hereditary factors, such as questionable embryologic and morphologic differences between the two races, greater frequency of myopia and trachoma among the Japanese, and inadequate dietary intakes of vitamins A and B and of calcium, and abnormal ration of calcium and phosphorus in the Japanese diet. John C. Long.

Kirschberg, L. S. S. Depth perception and flying ability. *Arch. of Ophth.*, 1946, v. 36, Aug., pp. 155-170.

This is an analysis of data gathered in the examination of trainees in the Royal Canadian Air Force. Binocular depth perception was measured with a modification of the Verhoeff instrument. It was found that with this instrument in a single test a subject's binocular depth perception could be classified as "good," "average," or "poor." Among 303 student pilots there was a strong indication that good visual acuity is an important factor in depth perception. In a series of 504 aircrew trainees it was shown that amplitude of fusion and depth perception scores were independent of one another. It was further shown that there was a relationship between the performance on the instrument used to measure amplitude of fusion (Worth Amblyoscope) and the instrument used to determine desire for fusion (Harman Diaphragm). It was not possible to demonstrate any definite relationship between desire for fusion and depth perception, nor was there a demonstrable relationship between depth perception scores and heterophoria. There was a complete lack of relationship between depth perception and flying ability. Also there was no relationship to flying ability and orthophoria or desire for fusion. John C. Long.

Lauber, Hans. The performance of the visual field. *Revue Bulgare d'Opht.*, 1943, v. 2, pp. 95-99.

The author presents a three-dimensional model that exhibits the characteristics of the visual field, a so called field island. The top of the island corresponds to the fixation point, the isopters are shown in planes, at successive levels. The blind spot forms a vertical channel which extends down to the zero-plane. (7 figures, references.)

Ludvigh, E., and Kinsey, V. E. Effect of long ultraviolet radiation on the human eye. *Science*, 1946, v. 104, Sept. 13, pp. 246-247.

In seven individuals, the foveal light-difference sensitivity and critical flicker frequency of each eye was tested before and after the exposure of the left eye only for five minutes to light which had been filtered so as to contain rays near 360 mμ. There was no statistically significant difference in the results as a consequence of the exposure, from which the authors conclude that ultraviolet radiations greater than 320 mμ encountered in nature are without deleterious effect upon those two functions of the human eye. (1 figure, references.)

Bennett W. Muir.

Maggiore, L. Device for doing dynamic skiascopy with a hand electric ophthalmoscope. *Ann. di Ottal.*, 1946, v. 73, March, pp. 183-187.

The device is essentially a plate of transparent glass and a 3-cm. opaque black disk with a central 3-mm. round sighthole. These are in a mounting for attachment to the ophthalmoscope handle in place of the ophthalmoscope head. The plate is mounted at an angle of 45° in front of the disk. Light from

the lamp in the handle is reflected by the polished surfaces of the plate into the patient's eye, and light reflected back from the fundus of the latter passes through the plate into the observer's eye behind the sighthole. Retinoscopy can thus be performed in the same manner and on the same optical principles as with a plain mirror with a central opening.

(The term "dynamic skiascopy" is used in contradistinction to Strampelli's "static skiascopy," but the method is the same as our ordinary retinoscopy.)

McCulloch, C., and Crush, M. Clinical aspects of stereopsis. *Arch. of Ophth.*, 1946, v. 36, Aug., pp. 171-188.

The authors report upon a series of studies conducted in the Royal Canadian Air Force. Stereopsis and suppression were measured in the synoptophore with specially prepared slides that gave quantitative measurements. Stereoptic acuity varied directly as the visual acuity. Decrease in stereoptic acuity accompanied increase in the amount of the suppression. Unilateral or bilateral myopia or myopic astigmatism with vertical axis reduced stereoptic acuity in proportion to the increase of the error. Acuity of stereopsis was reduced but could be maintained partially in myopic astigmatism with horizontal axis, any hypermetropic astigmatism, and in anisometropia. Acuity of stereopsis was not affected in hypermetropia. Increase in the size of the test objects improved stereoptic acuity. Increase in the separation of the test objects decreased stereoptic acuity. Convergence, heterophorias, age, and accommodation showed no correlation with acuity of stereopsis.

John C. Long.

Plicque, J. **Analysis of binocular vision.** *Ann. d'Ocul.*, 1946, v. 179, Feb., pp. 83-102.

Fixation in binocular macular vision and depth perception are greatly facilitated by the decussation of the macular fibers in the superior colliculus. The size of retinal images may be measured with the eiseconometer, the Remy diploscope, the apparatus of Gramont, or the stereoscope. Binocular perception of depth is an instantaneous phenomenon which depends upon bilateral integration of occipital lobe impulses derived especially from the macula. Depth perception may be altered by the stereoscope which changes the normal binocular relationship between accommodation, convergence, and distance estimation. A slight change of angulation and decentralization on stereoscopic charts changes the estimation of distance. Binocular vision is largely macular vision and therefore depends on cone function. Beyond a 15 degree radius from the macula peripheral vision is supplementary. Physiologic diplopia is of little importance in binocular vision. In the maintenance of binocular vision accommodation, convergence, and extraocular coordination of the extraocular muscles are essential. Conditions which affect the easy integration of the occipital macular impulses of both eyes such as anisomotopia, anisocoria, and conical cornea interfere with binocular vision. (References.)

Richardson, J. A., and Kinard, F. W. **Effects of vitamin A administration upon defective color vision.** *South. Med. J.*, 1946, v. 39, Oct., pp. 811-813.

Twelve healthy medical students were given fifty thousand units of vitamin A daily and seven were given placebos for a period of eight weeks. Improvement in color vision as tested with pseudoisochromatic charts was negligible.

I. E. Gaynon.

Sasiain, M. R. **The effect of altitudinal hypoxemia on the light sense, color sense, and the visual field.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Sept., pp. 721-737.

These studies were made in a pressure chamber, corresponding to an altitude of 5,000-5,500 meters. Below 4,000 meters the hypoxemia can be compensated and the normal physiologic functions maintained. Above 6,000 meters compensation is impossible and pressurized equipment is essential. The altitude of 4,500 to 5,000 meters represents an intermediate zone, in which the hypoxemia can be compensated to the extent of avoiding syncope, but not to the extent of eliminating all phenomena produced by it. The central visual acuity, ocular tension, and the caliber of the central retinal artery are not affected by altitude. In 25 young men without nutritional deficiencies the light sense was found diminished with altitude. The recuperation time after dazzling is shorter at an altitude than on the ground. In 80 out of 100 tests the light sense improved with dark adaptation, and in 20 it diminished in spite of dark adaptation. The color

sense was investigated in 70 young men of whom 64 had trichromatic color vision and six dichromatic. It was found that in normal trichromatic subjects the color sense is not affected by altitude. Dichromatic and protanopic subjects become more deuteranopic with altitude and deuteranopia is exaggerated. The visual field was tested on the Forster perimeter with 1-cm. objects, on 20 young men, of whom 14 were emmetropic and six were myopic. It was found that the visual fields for white, red, yellow, and blue become constricted with altitude. The degree of the constriction varies in different individuals, and for different colors; the average is between 4 and 10 degrees. The field for green shows a constant extension with 15 degrees as the maximum, and 1 degree as the minimum, and an average of five. This widening of the field for green is smaller, more regular, and constant, than the constriction for white and other colors. Ray K. Daily.

Sasiain, M. R. The situation of the far point of the emmetropic eye. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, April, pp. 362-366.

This laboratory investigation was made on 40 persons who focused for clearest vision while looking through a telescope with oculars ranging from minus six to plus six diopters. On the basis of this study, supported by a review of the literature the author concludes that the punctum remotum of the emmetropic eye in repose is not at infinity. The eye at rest is accommodated for a finite distance of about two meters, where the far point of the eye is. The eye is capable of a negative accommodation for fixation at infinity, the amplitude of which is 0.80 diopter as a maximum. The mechanism of negative

accommodation is as yet uncertain. (2 graphs.) Ray K. Daily.

Shevaley, V. E. A simplified prismoptometer. *Oftal. Jour. (Odessa)*, 1946, pt. 2, pp. 34-38.

Shevaley combined the two prisms, which constitute this instrument, in such a way that they can be placed in a trial frame behind the correcting lenses. This simplified arrangement makes easily available an otherwise expensive instrument. He believes that the instrument provides a reliable means for performing a rapid subjective refraction test. (7 illustrations.)

Van der Velden, H. A. The number of quanta necessary for the perception of light of the human eye. *Ophthalmologica*, 1946, v. 111, June, pp. 321-331.

A method for the determination of the number of absorbed quanta in the visual purple necessary for the perception of light in rod vision is described. From the observation of light flashes it is possible to fix this number without knowing anything about the part of light absorbed by the visual purple.

The experimental technique is described and the mathematical analysis of the data is discussed in detail. The agreement between theory and experiment is emphasized.

The experiments indicate that two effective quanta are needed for the creation of a light stimulus and that a co-operation between two rods which each have undergone a change of one light-quantum are essential. This is in accordance with the concepts of nerve physiology. (4 figures, references.)

Alice R. Deutsch.

Viallefont, H. **Entopic examination of the retinal arteries.** *Ann. d'Ocul.*, 1946, v. 179, March, pp. 127-130.

Oblique scleral transillumination through the closed lids preferably in the lower nasal quadrant, is followed by entopic visibility of the retinal vessels and disc. This is the familiar Purkinje phenomenon which may be easily demonstrated by pressing against the lower lid an ordinary electric ophthalmoscope with the head removed. Both eyes should be closed and the patient should look somewhat nasally, while the ophthalmoscope is moved in a rotary manner. The retinal vessels appear as brown lines on a dark pink background. By increasing the pressure of the ophthalmoscope on the eyeball, the author observed a bright stellate figure with undulating lines which appear and disappear synchronously with the radial pulse. The exact mechanism of this pressure reaction is not understood, nor why it radiates about the disc rather than the macula. Its further study is suggested in conditions with altered intraocular and intravascular pressure relationships, such as glaucoma, aortic insufficiency, and vascular hypertension.

OCULAR MOVEMENTS

Davies, C. **Orthoptic treatment of convergence insufficiency.** *Canad. M. J.* 1946, v. 55, July, pp. 47-49.

Convergence insufficiency bears no relationship to refraction, and is not cured by correcting refractive errors, except occasionally in under-corrected myopia and over-corrected hypermetropia. Prisms will not cure it because they do not develop a convergence reserve. Operation has not proved satisfactory in the author's experience. Extreme insufficiency, however, may become heterophoria. Convergence insufficiency may occur at any age from adolescence to the late fifties. Subjective symptoms are fairly constant. Measurements with Maddox rod and screen test are not diagnostic. They do not indicate convergence reserve. Repeated convergence on a test object is a quick and accurate test for convergence insufficiency.

Seventy percent were cured. The failures usually had complicating factors such as aniseikonia, physical or nervous disturbances. Cures were only possible when there was a good fusion amplitude with fusion reserve and a good recovery point. Some people became comfortable after a few treatments and failed to return until their symptoms recurred one to three years later. The correction of convergence insufficiency with esophoria was found to take the longest time because correct abduction had to be taught as well as adduction. Some typical cases are reported in brief.

Lijó Pavía, J. **The orthofusor, amblyoscope, and prisms; indispensables in the treatment of strabismus.** *Rev. Oto-Neuro-Oft.*, 1945, v. 20, Nov.-Dec., pp. 142-154.

To treat properly any given case of strabismus it is necessary to determine the visual capacity, the surgical need and procedure, to prescribe the proper optico-prismatic aid, and to reëducate

or perfect the visual capacity through the amblyoscope and orthofusor. The orthoptic training reduces any existing amblyopia, treats abnormal retinal correspondence, and encourages binocular single vision. The author advises stimulation of binocular vision soon after (10 days) operation has been performed, and the early use of occlusion. The angle of anomalous retinal correspondence must be determined and overcome early. (Such a condition may be associated with triplopia.) Finally, the depth perception is investigated and retrained with stereograms. Eleven patients are described. They had strabismus with or without abnormal correspondence, and were definitely helped by orthofusor training. (Bibliography, 11 photographs.) Edward Saskin.

Santoro, Nicola. Tuerk's syndrome associated with Marcus Gunn phenomenon. *Riv. Oto-Neuro-Oft.*, 1941, v. 18, no. 4, pp. 300-311.

A 13-year-old girl had fibrous degeneration of her right external rectus muscle, that resulted in retraction of the right eye upon adduction, and made abduction of the right eye beyond the midline impossible. (Tuerk's syndrome). There was also ptosis of the right upper lid which could be raised only if the patient opened her mouth or performed chewing movements (Marcus Gunn phenomenon). The author does not believe that this rare combination of muscular disturbances was produced by a single pathogenetic factor. He prefers to explain the retraction phenomenon as a birth injury, and the jaw winking phenomenon by a mechanism of nervous synergy, the site of which he does not determine. (6 photographs.)

CONJUNCTIVA

Aguilar, Jose. A case of resistant pneumococcus conjunctivitis. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Nov., p. 1001.

A pneumococcus conjunctivitis that had resisted all forms of local therapy for three months responded in a week to sulfathiazol compresses. The diagnosis and the cure were verified bacteriologically. Ray K. Daily.

Amat, M. M. A rare complication of vernal conjunctivitis. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Nov., pp. 994-1000.

A 41-year-old woman had central corneal ulcers of both eyes caused by the irritation of the excrescences of vernal conjunctivitis. In the left cornea the untreated ulcer led to corneal perforation. In the spring she had a dermatitis of the hands and face. Because of corneal ulceration the left eye was bandaged for a long time; this not only resulted in the healing of the corneal ulcer, but the conjunctival excrescences disappeared, and the conjunctiva assumed a normal appearance. The right eye, which remained open had at the same time a florid vernal catarrh. The author advocates the Blascovics operation in this disease. Ray K. Daily.

Baxter, C. R. Reiter's disease. *Brit. M. J.*, 1946, Dec. 7, p. 858.

A case of Reiter's disease is interesting because all of the symptoms except diarrhea and hematuria were exhibited and for the sequence of their appearance—conjunctivitis, urethritis, then

polyarthritis and keratoderma coincidentally, and a concomitant recurrent iritis that was preceded by intraocular hemorrhage.

F. H. Haessler.

Bushmich, D. G. Tissue therapy of trachomatous pannus. *Oftal. Jour.* (Odessa), 1946, pt. 2, pp. 22-25.

This form of therapy was applied to trachomatous pannus by Filatov in 1936. Implantation of preserved cadaver mucous membrane from the lip and conjunctiva led to gratifying results. Later Filatov and his school tried implantation of preserved cadaver skin into the conjunctiva and in the skin of the temple, autotransplantation of preserved mucous membrane from the lip, implantation of preserved sclera on the eyeball, and subconjunctival implantation of preserved cartilage. The results were gratifying in all cases. Implantation of placenta and intramuscular injections of cod liver oil were included among the therapeutic procedures. Within recent years Filatov began to experiment with products of vegetation placed in unfavorable environment; he used principally an aqueous extract of leaves of aloes. Kalfa, in experimenting with this extract found considerable absorption of the infiltration of the lids after the subcutaneous injections of extract of aloes, and subcutaneous implantation of preserved skin in 32 patients. These procedures lead to a retrogression of pannus, increased transparency of the cornea, and a diminution of infiltration in the lids. There was no recurrence of the disease.

Hayes, F. B., and Chamberlain, R. D. Meningococcal conjunctivitis. *U. S. Naval Med. Bull.*, 1946, v. 46, May, pp. 758-760.

A unilateral acute purulent conjunctivitis, with intra- and extracellular gram-negative diplococci is described. Shortly after the onset of the conjunctivitis, the patient developed purulent meningitis. Cultures revealed meningococcus type I in eye secretions and spinal fluid. The patient recovered after penicillin therapy. Benjamin Milder.

Kamel, S. Pterygium. Its nature and a new line of treatment. *Brit. Jour. Ophth.*, 1946, v. 30, Sept., pp. 549-563.

Histologic study of pterygium revealed the presence of an ordinary hyaline degeneration with much elastic connective tissue. Pterygium begins as a common exposure conjunctivitis. When the inflammation attacks the cornea, a chronic kerato-conjunctivitis results and a pterygium begins to form. Fibrous tissue is laid down in the area and when this contracts, it pulls a fold of loose conjunctiva toward the rigid cornea. The neoplastic and degenerative theories of the etiology of pterygium are untenable.

The McReynolds operation is followed by recurrence in 30 to 50 percent in Egypt. In inactive pterygium the author merely snips off the head of the growth. When a pterygium is active the head is shaved off, and the growth is undermined throughout its length.

but it is not dissected from the rest of the conjunctiva. After the undermining it is allowed to fall back into place. Its under surface is carefully cauterized with phenol and the eye is bandaged for a few days. The purpose of the undermining and the cautery is to destroy the fibrous bands which have pulled the fold toward the cornea. In 600 cases there has not been a single recurrence.

Morris Kaplan.

Lavery, F. S. Sulphonamides and penicillin in the treatment of trachoma. *Brit. Jour. Ophth.*, 1946, v. 30, Oct., pp. 591-594.

End results of 13 cases of proven trachoma treated with sulphonamides and with penicillin are tabulated. Eight patients were given a sulfonamide for trachoma and five were treated with penicillin. In each group inclusion bodies persisted in four patients.

Lopez, P. M. The forms, types, and therapy of simple superficial chronic conjunctivitis. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Nov., pp. 981-993.

For proper treatment of chronic conjunctivitis it is necessary to make a thorough ocular and general examination. Diseases of the lacrimal apparatus, Meibomitis, errors of refraction, toxic products originating from disturbances of the various organs, and allergy may be etiologic factors. For local therapy he prefers superficial scarification of the cornea followed by the application of alum or copper sulphate pencil. This is followed by the usual colyria and ointments. Diaphanoscopy is urged for the examination of the Meibomian glands, which are a frequent source of chronic conjunctivitis.

Ray K. Daily.

Miller, A. R., and Blower, D. E. Primary diphtheria of the conjunctiva. *Lancet*, 1946, v. 2, Sept. 7, pp. 345-346.

Two cases of primary diphtheria of the conjunctiva are reported by the authors. The first, in a girl, three years of age, manifested itself by nasal and conjunctival discharge. Diphtheria bacilli were found in the eye secretions only. Antitoxin cured the patient promptly. The second case occurred in this child's five-year-old brother.

CORNEA AND SCLERA

Bassi, G., and Jona, S. The ocular manifestations in human alactoflavinosis. *Boll. d'Ocul.*, 1945, v. 24, Jan.-March, pp. 3-18.

A boy, 12 years of age, had poor vision as long as he could remember. His vision was 1/10 in each eye. The biomicroscopic examination showed a pericorneal injection and most extensive vascularization of the entire cornea. Intense photophobia and lacrimation existed. The condition of the eyes improved after treatment with lactoflavin. After a long discussion the writer concludes that the presence of such general manifestations as glossoptrophy and goniostomatopathy and the good result obtained from the specific treatment justify the diagnosis, namely alactoflavinosis. (6 illustrations, references.)

Bonnet, P. A diffuse hyperplastic papillomatous tumor of the cornea originating from an old pannus. *Revue Bulgare, d'Opht.*, 1943, v. 2, pp. 44-54.

The author reports the clinical and

pathological description of a papillomatous growth in a cornea, in an eye with trachomatous pannus. He discusses the possible treatment and prefers temporary blepharoraphy to any other treatment. (4 figures.)

Alice R. Deutsch.

Bowles, L. L., Allen, L., Sydenstricker, V., Hock, C., and Hall, W. The development and demonstration of corneal vascularization in rats deficient in vitamin A and in riboflavin. *J. Nutrition*, 1946, v. 32, July, pp. 19-35.

About 500 Wistar strain rats were used in this study. Some were placed on riboflavin and others on vitamin A deficient diets. The corneas were studied after the ascending aortas had been injected with 5 ml. of india ink.

In riboflavin deficiency conjunctival edema and congestion, usually with photophobia, was the first ocular change, followed after a week by marked congestion of the limbal vessels and occasionally by faint nebula. Soon thereafter capillary "sprouts" began to invade the cornea, in 60 percent from the superior nasal quadrant, in 20 percent from the 12-o'clock meridian above, and in 20 percent from the superior temporal quadrant. A few days later, intense edema and corneal opacification occurred, which obscured the progress of the vascularization. This subsided after one or two weeks, when the cornea was heavily vascularized, often with anastomoses in the central portion. The pattern was more of the terminal loop type and less of the dendritic. This vascularization was relatively easily distinguished from the spontaneous vascularization that was found in 4 of the 500 rats.

In vitamin A deficiency, conjunctival edema and congestion with photophobia, occurred first, then xerophthal-

mia, with an opaque and partially desquamated cornea. Three to seven days later the cornea was diffusely opacified, and capillaries were seen peripherally, usually of the dendritic type, which formed a dense peripheral band. Then edema and leukocytic infiltration often progressed so that the vessels became invisible. (2 plates, 12 figures, references.)

Cantuliera, J. A. Herpetic keratitis. Report of cases. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Sept., pp. 776-790.

A review of the literature on the etiology and therapy of herpetic keratitis is presented. Two cases of dendritic keratitis and two of superficial punctate keratitis treated with satisfactory results with vitamin B₁ are reported.

Ray K. Daily.

Cavara, Vittoriano. Severe and severest types of herpetic keratitis. *Revue Bulgare d'Opht.*, 1943, v. 2, pp. 65-73.

After a short review of the classic forms of herpetic keratitis and related types the author describes observations of his own with especial emphasis on two eyes with dense corneal infiltrations of insidious onset which because of their herpeticiform fluorescein staining, loss of corneal surface sensitivity, and intensive neuralgic pain were considered herpetic in origin. He draws attention to the fact that a severe keratitis of unknown etiology may be herpetic. (References.)

Alice R. Deutsch.

Colombo, Gianluigi. Cases of epidemic nummular keratoconjunctivitis in Milan. *Boll. d'Ocul.*, 1946, v. 25, Jan.-June, pp. 297-302.

The writer reports three cases of this affection in members of the same fami-

ly. The patients, two adult women and a man, were treated with sulfathiazole preparations, zinc sulphate, mydriatics and vitamin B₁ with improvement of the conjunctival symptoms but with no marked effect on the corneal symptoms which had began two weeks after the beginning of the affection and two months later were still present. Probably an ultravirus is the causative agent of the disease. In 40 percent the symptoms are limited to the conjunctiva. The disease manifests itself in cold and damp periods, affects adults and can be unilateral. There may be preauricular adenitis, photophobia, catarrhal exudation and all other symptoms of acute conjunctivitis. The corneal manifestations begin with small round numerous grayish infiltrations situated mostly in the pupillary zone. The epithelium remains intact, the corneal sensibility is slightly diminished, and no marked pericorneal injection is visible. The vision is affected greatly. The writer gives a differential diagnosis from other types of conjunctivitis and keratitis. Melchior Lombardo.

Dejean, C., and Sedan, J. A clinical and experimental study of corneal lesions caused by indelible pencil and their treatment. *Revue Bulgare d'Opht.*, 1943, v. 2, pp. 75-83.

Corneal injuries caused by indelible pencils may cause aseptic necrosis. The basic colors are more dangerous than the acid dyes because they penetrate faster and have a selective affinity for the nuclei of the cells.

Two clinical observations and fourteen experimental lesions in guinea pigs are described to demonstrate the necrotizing action of aniline dyes. Deep corneal ulcers and a widespread interstitial keratitis occur in untreated eyes. A thorough and immediate mechanical

cleaning of the wound, followed by lavage with 95-percent alcohol, considerably improve an otherwise unfavorable outcome. Alice R. Deutsch.

Ershkovich, I. G. Keratoplasty in complicated leucomas, following war-injuries. *Oftal. Jour. (Odessa)*, 1946, pt. 2, pp. 18-21.

Keratoplasty in war injuries is not widely used, because of the severe injuries of the ocular tissues and because of the density of the leucomata. Ocular perforations, which form the greatest number of injuries, were inflicted principally by mine fragments, and along with corneal destruction produced havoc in the deeper structures of the eye. The results of such damage are dense large leucomas, matted with the iris, and with dense cicatricial membranes behind. There is frequently an organized exudate in the anterior chamber. The lens is opaque or partially absorbed. The deeper changes are obscured by the cloudy media, but usually there is organized exudate in the vitreous, traumatic chorioretinitis, proliferative retinitis, optic atrophy, and sometimes retinal detachment. In addition there is frequently flattening of the leucoma or of the entire anterior ocular segment, ectasia of the leucoma, and secondary glaucoma. Such eyes are not considered suitable for keratoplasty. Occasionally, however, keratoplasty in combination with other operations and with persistent tissue therapy may bring about significant visual improvement, which liberates the patient from invalidism, and may even restore a degree of vocational competence. He urges that the surgical indications be extended, and that patients with corneal scars be given the benefit of persistent therapy even in the presence of synechia, cicatricial membranes, vitre-

ous opacities and changes in the fundus. (2 illustrations.) Ray K. Daily.

Filatov, V. P. **Perspectives in keratoplasty.** *Vestnik Oft.*, 1946, v. 25, pt. 1, pp. 34-38.

Filatov credits priority in keratoplasty to Pirm and Elschmig, and claims as his own contribution simplification of technic and utilization of cadaver cornea. On the basis of his experience with over 1,000 eyes he outlines a series of problems under investigation. The most unmanageable complication in keratoplasty is glaucoma, and one of the great needs is an effective antiglaucomatous operation. Improving the transparency of the graft and the biologic conditions of the leucoma is accomplished best by superficial corneal grafts combined with tissue therapy. Removing the opaque anterior corneal layers sometimes gives very satisfactory results, particularly if combined with tissue therapy. The transplantation of the entire cornea for staphylococcal infection is only in its initial stage of investigation. The correlation between the microscopic picture of the leucoma and the results of keratoplasty, and on the optimal period of preservation of cadaver eyes is being studied. Keratoplasty in war-injured eyes is not satisfactory, and studies should be made to determine the optimal period of surgery, the preoperative preparation, and the reaction of traumatized eyes. The possibilities of heteroplasty are indicated by the work of Petrociantz, who succeeded with transplantation of dog cornea on cats. Seltzer's and Shereshevski's work with transplantation of cornea preserved in formalin needs further investigation. The chaotic reports of keratoplasty do not permit an accurate evaluation of the surgical procedures. Filatov urges that corneal

leucomas be classified according to their extent and density, and that the surgical results be carefully recorded in relation to the state of the corneal leucoma. The comparison of opacities following interstitial keratitis with dense corneal leucomas obviously leads to confusion. Ray K. Daily.

Gardiner, P. A. **Corneal vascularization in chronic disease.** *Brit. Jour Ophth.*, 1946, v. 30, Oct., pp. 581-589.

In view of the frequent appearance of corneal vascularization in deficiency diseases 191 patients with duodenal ulcer, rheumatoid arthritis and fibrositis, skin diseases, osteo-arthritis, and some other gastro-intestinal diseases were studied and compared with a control group of healthy persons and persons who had trivial illness. It was shown that the more severe the disease, the more vascular the cornea. However, some vascularisation, often marked, was found in persons with trivial illness. None was found in healthy subjects nor in patients with diseases of functional origin. Possibly the phenomenon could be used to differentiate organic from functional diseases. (5 tables.) Morris Kaplan.

Girones, E. A. **Keratitis punctata.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Sept., pp. 768-775.

A review of the literature, a description of the clinical symptoms, and a discussion of the etiology are presented. The cases seen by the author occurred after an epidemic of acute Koch-Weeks conjunctivitis and were in close relation to an epidemic of upper respiratory infection. Accumulated data on the identity of the Koch-Weeks and the influenza bacillus, suggest that possibly this bacillus is the cause of keratoconjunctivitis producing the inflammation

through the liberation of toxins or an ultravirus. Additional evidence to support this belief is the fact that grippe often begins with conjunctivitis, and that some patients with Koch-Weeks conjunctivitis have severe constitutional symptoms. The onset of the punctate keratitis is sudden, its evolution is slow, and therapy is of little avail. (6 illustrations.) Ray K. Daily.

Golovina, A. C. **Keratoplasty in leucoma in veterans.** *Vestnik Oft.*, 1946, v. 25, pt. 1, pp. 43-46.

Golovina reports six cases of keratoplasty in four veterans with severely injured eyes and extensive intraocular damage. Five eyes recovered some vision. Golovina attributes much importance to preoperative and postoperative tissue therapy. Ray K. Daily.

Gruber, Max. **Cornea verticillata. (Second communication.)** *Ophthalmologica*, 1946, v. 112, Aug., pp. 88-91.

To a previous report Gruber adds a second family in which cornea verticillata occurred, a condition first described by Fleischer. It was observed in both eyes of a woman, 56 years of age, and of one adult son, and daughter. It is probably an unusual hereditary variation of physiological character. The manner of transmission is not certain. (6 figures, 1 family tree, references.) F. Nelson.

Kinsey, V., and Grant, W. **Determination of the rate of disappearance of mustard gas and mustard intermediates in corneal tissue.** *J. Cl. Invest.*, 1946, v. 25, Sept., pp. 776-779.

The rate of disappearance of H (mustard gas) in corneas in vitro at 23 and 37 degrees centigrade was determined by analysis of cyclohexane-kerosene extracts. For these two temperatures, the half-life of H was found

to be approximately 13 and 3 minutes, and the over-all half-life of H and its monochloro hydrolysis product was 18½ and 4 minutes, all respectively.

The effect on corneal tissue was measured by subsequently determining inhibition of swelling of the corneal pieces when placed in water. It was found that the effect was proportional to the number of chlorides of both H and H hydrolysis intermediates available for replacement.

The findings indicate that therapeutic agents designed to react with H within tissues would be without benefit unless used within 3 to 5 minutes after contact with the vesicant.

Theodore M. Shapira.

Lohlein, Walter. **Keratoplasties in keratoconus.** *Revue Bulgare d'Ophth.*, 1943, v. 2, pp. 101-111.

Three successful keratoplasties in keratoconus are reported. The author discusses the special indications, difficulties and results of keratoplasties in this disease.

The avascularity of the cornea is an advantage for the operation. The eccentric location of the tip of the conus and the thinning of the cornea make the operation more difficult. Early surgery and a large transplant (not smaller than 5 mm.) are recommended so that the whole thinned area is removed. A larger transplant increases the danger of irregular fitting and the formation of a fistula. Alice R. Deutsch.

Matteucci, P. **Corneal lesions in Hodgkin's disease.** *Amer. Jour. Ophth.*, 1947, v. 30, Feb., pp. 136-142. (2 figures, references.)

Mazzoletti, Giorgio. **A case of familial degeneration of the cornea of the nodu-**

lar type. *Rassegna Ital. d'Ottal.*, 1941, v. 10, March-April, p. 171.

A perforating keratoplasty was done on the right eye of a 66-year-old man whose vision was reduced to light perception in each eye. Microscopic examination showed disintegration of Bowman's membrane, hyperplasia of the epithelial cells with changes in the basal layer. The stroma presented an amorphous, granular substance, partially condensed into droplets. Differential staining showed that there were two kinds of substances with opposite reactions, which, however, did not correspond to the description of a basophilic stain below Bowman's membrane and an acidophilic stain in the epithelial cells. (2 figures and bibliography.)

E. M. Blake.

Roshchin, V. P. The biologic indicator in 124 cases of keratoplasty. *Vestnik Oft.*, 1946, v. 26, pt. 1, pp. 47-48.

The author presents an analysis of the correlation between the type of leucoma and the transparency of the graft in 124 cases of keratoplasty. In leucoma simplex a transparent graft was obtained in 60 percent of cases, in leucoma adherens in 38 percent, and in leucoma totale in 17.9 percent.

Ray K. Daily.

Samoilov, A. J., and Shivarova, E. D. The role of sensitivity of a leucoma in the transparency of the graft in keratoplasty. *Vestnik Oft.*, 1946, v. 25, p. 1, pp. 38-43.

The tabulated data show that corneal sensitivity, as an indication of the trophic condition of the cornea, was an important prognostic indicator of the final visual result in 20 cases of keratoplasty. The transparency of the grafts was in direct relation to the corneal sensitivity of the host. It is advisable

to increase the corneal nutrition and sensitivity preoperatively with physiotherapy and tissue therapy.

Ray K. Daily.

Smelser, G. K., and Ozanics, V. Effect of quick freezing at very low temperatures of donor tissue in corneal transplants. *Proc. Soc. Exper. Biol. and Med.*, 1946, v. 62, June, pp. 274-277.

To test the late results of frozen material as compared with living transplants, a series of corneal transplantations was done on rabbits. The corneas were frozen in isopentane, and transferred to liquid nitrogen, where they remained for one hour to four days. Not one of the operations was successful; all the transplants became opaque eventually. In a control series of 22 cases all eyes remained clear. The use of frozen tissue is no handicap in the technical details of the operation. (2 figures, references.)

Bennett W. Muir.

Sourdille, G. P. Technique of corneal grafts in man. *Arch. d'Ophth.*, 1946, v. 6, no. 3, pp. 273-283.

Sourdille reviews the various techniques in keratoplasty and discusses their advantages and disadvantages. He mentions the value of partial non-penetrating grafts in some cases as a preparation for the classical whole-thickness corneal graft and their value in the treatment of recurrent pterygium, lipid degeneration, and dystrophies of the cornea. Penetrating grafts yield a satisfactory percentage of permanently clear grafts. He emphasizes the importance of technique in obtaining clear grafts and describes his own in detail. To obtain his grafts he uses an Elliot trephine with a diameter of 5 mm. and with the bevel on the out-

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Adamantiades, B. Thrombophlebitis as a fourth symptom of recurrent hypopyon iritis. *Ann. d'Ocul.*, 1946, v. 179, March, pp. 143-147.

A fourth symptom is added to the syndrome of Behcet (hypopyon iritis, ulcers of the mouth and ulcers of the genitals). Venous retinal hemorrhages caused by thrombophlebitis may precede the other elements of the syndrome, especially the hypopyon iritis. Thrombophlebitis may also exist in other parts of the body. The etiologic factors may be varied and multiple, with or without an allergic factor, and may be brucellosis, staphylococic septicemia, tuberculosis, and virus infections of unknown origin. The assumption of an allergic factor helps explain the periodicity, sudden onset, relatively short duration, and the coexistence of dermal erythema, and ulcers of the mouth and genitals. Recurrences have frequently followed exposure to cold. The ocular disease resembles a condition observed in horses. In the first case reported, the ocular condition was considered tuberculous and was treated with methylic antigen, and later with penicillin. Vision was totally lost in both eyes from recurrent attacks during four years. In the second patient thrombophlebitis of the lower extremities and retina accompanied the other units of this syndrome. Arruga, H. A case of essential atrophy of the iris. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, April, pp. 233-237.

Arruga reports a case of essential atrophy of the iris, in a woman 25 years

side. The trephine used for the recipient eye, however, is beveled on its inner face. He has not used mechanical trephines. To protect the iris and lens he has used the knife designed by Nicetic to make a double corneal section. Other instruments include large spatulas, narrow keratomes, and corneal scissors.

In preoperative preparation Sourdille stresses the importance of removing all sources of infection such as lacrimal disease or conjunctivitis. He recommends the coagulation of superficial vessels such as occur in phlyctenular keratitis or, if there is a pannus present, its removal by dissection. Iris adhesions, either to the cornea or to the lens, if extensive, should be removed by iridectomy or by synechotomy. Intraocular tension must be normal preoperatively. For anaesthesia he supplements topical applications of cocaine and adrenalin with retrobulbar injection of procaine. He holds the graft in place by means of a narrow strip of conjunctiva. The source of the graft is important and grafts from eyes with absolute glaucoma and traumatic corneal lesions should be avoided. Postoperative care includes binocular dressings for ten or twelve days, with the first dressing on the fourth or fifth day. The conjunctival strip is allowed to retract on the eighth or ninth day.

The main difficulties in the operation seem to result from poor trephines, from secondary glaucoma, from iris-lens adhesions, from vitreous in the anterior chamber, from secondary expulsion of the graft, and from necrosis of the graft. The author discusses these complications and their treatment. He concludes that in spite of them the operation yields a high percentage of satisfactory results.

Phillips Thygeson.

of age, with otherwise negative general and local findings. Reference is made to Zentmayer's and DeSchweinitz's cases which were similar to this case, and to Arnold's case, which terminated in glaucoma. (3 illustrations.)

Ray K. Daily.

Bothman, Louis. Allergic iritis. *Illinois M. J.*, 1946, v. 89, March, p. 124.

Bothman reviews the literature and reports six cases of iritis with presumptive evidence of allergic etiology. Repeated studies for focal infection were negative. Treatment with atrophine, fever, and calcium failed to prevent recurrences. All patients were highly allergic to several agents. All had involvement of the cornea with superficial infiltrates at one time or another. One has been under controlled treatment with no recurrences for six years.

John B. Hitz.

Bushard, W. J. Intraocular malignant melanomas of the choroid. *Minnesota Med.*, 1946, v. 29, Oct., pp. 1005-1007.

The subject is reviewed in brief. The symptomless stage, during which much valuable time so necessary in making an early and exact diagnosis is often lost, receives considerable attention. Most fortunate is the patient in whom the growth occupies the macular area. More often the late toxic signs of glaucoma or iridocyclitis arouse the patient, but the confusing picture may at least temporarily lead to the wrong diagnosis.

Three cases are presented by the author. In one an extensive bullous detachment settled down over a circumscribed elevated mass after a subconjunctival scleral puncture. Unilateral detachment, congestive glaucoma, iridocyclitis, disturbed central vision in

one eye without obvious explanation, and phthisical globes call for particular effort in determining presence or absence of intraocular neoplasm.

Francis M. Crage.

Carlevarlo, G. Bilateral ocular manifestations in the heterochromia of Fuchs. *Rassegna Ital. d'Oftal.*, 1941, v. 10, March-April, p. 203.

The author presents four cases of heterochromia iridis and points out that the characteristic changes—precipitates on the posterior corneal surface, partial disappearance of the pigment ring of the iris, and numerous lenticular opacities—are present not only in the heterochromic eye, but to a lesser degree in the other eye. Cataract extraction is not contraindicated and the histologic examination of one lens so studied disclosed nothing unusual. (1 figure.)

E. M. Blake.

Charlin Vicuña, Carlos. Tuberculin-sensitive iridocyclitis. *Arch. Chilenos de Oft.*, 1945, v. 2, Nov.-Dec., pp. 28-30.

Spectacular improvement of bilateral iridocyclitis occurred in a woman of 28 years who was treated with extremely minute doses of tuberculin weekly, 0.1 c.c. of a "34 zero" solution (see Torres Estrada, *Bol. del Hosp. Oft. de Ntra. Sra. de la Luz*, 1944, July-Dec., page 163; abstracted *Amer. Jour. Ophth.*, 1945, v. 28, p. 1063).

W. H. Crisp.

Cortes, Hernan. Ulcerated gumma of the iris. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Jan., pp. 56-58.

Cortes reports a case of gumma of the iris which healed with pupillary occlusion and cyclitic cataract. For cosmetic reasons, against medical advice, the patient insisted on a cataract extraction. The surgical result was a

vascularized scar with the iris drawn into the incision. Ray K. Daily.

Cristini, Giuseppe. **Angioma of the choroid.** Riv. di Oftalm., 1946, v. 1, June, pp. 374-391.

The author reports a case of angioma of the choroid and discusses its differential diagnosis and pathogenesis. (8 photomicrographs.) K. W. Ascher.

Della Casa, Franz. **A metastatic abscess in the anterior chamber in chronic osteomyelitis.** Ophthalmologica 1946, v. 3, Feb.-March, pp. 152-155.

An abscess in the anterior chamber in a patient with osteomyelitis of the tibia and humerus is described. The hematogenous metastasis was apparently provoked by mild trauma. An embolus was probably located in the intrascleral plexus. (Colored plate.)

Alice R. Deutsch.

Diaz-Caneja, E. **Tubercle of the choroid in tuberculous meningitis.** Arch de la Soc. Oft. Hisp.-Amer., 1945, v. 5, July, pp. 511-518.

Recent studies have demonstrated that choroidal tubercles are demonstrated in only 10 percent of patients with tuberculous meningitis.

J. W. McKinney.

Dominguez, D. D. **Migrating ciliary nodules on the retina.** Arch. de la Soc. Oft. Hisp.-Amer., 1946, March, pp. 265-268.

Von Szily's article on Wandertuberkel, published in the Klin. Monats. f. Augenheil. in 1931 is abstracted, reference is made to Krückmann's article on the subject, and one of these rare cases is reported. A woman, 62 years of age, with a bilateral iridocyclitis, was found to have in the lower periphery of both fundi two white slightly elevated foci,

which were regarded as foci of choroiditis. She recovered and returned two years later with an attack in the right eye. Fundus examination at this time revealed no trace of the former choroidal foci in the left eye. In the right eye were two fresh foci of choroiditis in a similar situation. They were nodular in structure, greyish-white, sharply circumscribed and projected definitely above the surface of the retina. One of them was located over a small retinal vessel. The situation of the nodules excluded the diagnosis of retinitis or choroiditis and they were diagnosed as nodules that were detached from the ciliary body and had become fixed on the retina. Dominguez does not agree with Szily that this form of propagation of a lesion of the ciliary body towards the posterior pole is limited to tuberculosis and believes that iridocyclitis of any etiology may extend in this manner. He therefore suggests that the designation of "migratory ciliary nodules," without etiologic commitments is a better term for this phenomenon.

Ray K. Daily.

Duthies, O. M. **A case of congenital cyst of the iris.** Trans. Ophth. Soc. U. Kingdom, 1944, v. 64, pp. 244-247.

In a patient, 17 months of age, a congenital cyst of the iris was removed.

The lesion proved to be a simple cyst of myxomatous tissue lined by pigmented cells. Beulah Cushman.

Enciso, M. M. **A sarcoidal sarcoma discovered incidentally.** Arch. de la Soc. Off. Hisp.-Amer., 1946, v. 6., Jan., pp. 64-68.

An eyeball enucleated with the diagnosis of subacute metastatic uveitis was found to contain a choroidal sarcoma as well as metastatic uveitis. The diagnosis was confirmed by histo-

logic examination. The author believes that the two affections were purely coincidental. (Photomicrograph.)

Espíldora Luque, C. Sympathetic ophthalmia consecutive to subconjunctival rupture of the sclera. *Arch. Chilenos de Oft.*, 1945, v. 2, Nov.-Dec., pp. 26-28.

A man of 33 years was struck in the right eye with a fist. The subconjunctival rupture of the sclera extended from the ciliary region for about a centimeter backward, in the upper outer region of the globe. There was no hernia of the uvea, nor any suggestion that the crystalline lens had been luxated subconjunctivally. The scleral gap was completely covered by conjunctiva. Total hyperemia prevented internal examination. Vision was reduced to perception of light, with poor projection. The patient disappeared 12 days after the injury, the eye in apparently good condition, although the vitreous was cloudy. Two months later he returned with vision reduced to shadows in the other eye, which had previously been normal. The clinical appearance was that of a sympathetic ophthalmia of the posterior type, but the author doubts whether it would have proved anatomically to be of this character. While undergoing study in the clinic, the patient died of acute yellow atrophy of the liver, and apparently the eyeball was not sectioned.

W. H. Crisp.

Figueiredo, N. P. de. Iritis secondary to dental abscess (and ? crystalloiditis). *Rev. Brasileira de Oft.*, 1946, v. 5, Sept., pp. 33-36.

In addition to iritis with whitish spots in the upper and lower angles of the anterior chamber (a sort of hypo-

pyon), there was an irregular pyriform formation almost filling the pupillary area and resting on the crystalline lens. This formation underwent resolution after removal of the tooth. (2 diagrams, references.)

W. H. Crisp.

Franceschetti, A. Rheumatic eye diseases. *Ophthalmologica*, 1946, v. 111, Apr.-May, pp. 242-269.

The author reviews the different forms of rheumatic disease and their ocular manifestations. He stresses the importance of ocular diagnosis for the classification of an accompanying joint lesion. Severe acute rheumatic disease rarely involves the eyes, but chronic progressive polyarthritis does. There is apparently no connection between arthritis deformans and iridocyclitis. An exact classification of joint disease, therefore, is an essential prognostic and therapeutic factor.

The clinical appearance of chronic polyarthritis is different in children than in adults. An insidious iridocyclitis with cataract and band-shaped keratitis speaks for a chronic polyarthritis in children, most often of the type Still. A serofibrinous surface iritis and a remarkably increased sedimentation rate favors the diagnosis of rheumatic or tuberculous disease in adults.

The different theories about the origin of rheumatic disease and the difficulties in diagnosis are mentioned. A description of the manifestations in the ocular tissues is given, as well as an outline for its treatment. (10 figures, references.)

Alice R. Deutsch.

Goldmann, H. The drainage of the aqueous in man. *Ophthalmologica*, 1946, v. 3, Feb.-March, pp. 146-154.

The appearance of two kinds of veins, one filled with clear fluid, the other with alternating stripes of fluid and

blood, the permanent location of those veins mostly on the nasal and temporal sides of the episclera, the pulsating current of the clear fluid and its increase in amount with pressure on the globe are signs of the constant drainage of the aqueous through Schlemm's canal into the episcleral veins. The pressure which the filtration-angle opposes is very low because the normal variation of the ocular tension is transmitted to the veins and is not lowered by passing through the filtration network. The difference in tension which regulates the outflow of the fluid must be very slight. The resistance of the angular network in the chamber angle must be insignificant and the height of the resistance occurs at the junction of Schlemm's canal and the finest episcleral veins. This clarifies the problem of the effectiveness of a very small iridectomy.

Alice R. Deutsch.

Guglienetti, Luigi. **A melanosarcoma of the choroid with pigmentation of the vitreous.** *Revue Bulgare d'Opht.*, 1943, v. 2, pp. 91-94.

The author describes the clinical and pathologic findings in an aphakic eye in which a melanosarcoma was found. An unusual finding was the diffuse pigmentation of an otherwise normal vitreous. The sector of the conjunctiva corresponding to the tumor was also very much infiltrated with pigment. There were no signs of perforation. The pigment in the vitreous consisted of black punctate masses, partly floating, partly adherent to the retina over the apex of the tumor. They were also seen with the slit-lamp.

Alice R. Deutsch.

Jona, Sergio. **Clinical and biomicroscopic study of three cases of congenital, bilateral aniridia in the same fami-**

ly. *Rassegna Ital. d'Ottal.*, 1941, v. 10, May-June, p. 303.

The three members affected with congenital bilateral aniridia were the mother and two daughters. One son was unaffected. Jona discusses the different theories as to the development of this anomaly. Concomitant changes are nystagmus, macrocornea, microcornea, marginal corneal opacity different from embryotoxon, congenital and acquired lens opacities, degeneration of the vitreous, and uncertain foveal reflex. An Elliot trephine in one eye failed to reduce the glaucoma and removal of the lens is recommended in similar cases.

In one patient, where the zonular fibers were visible, observations were made on the act of accommodation. (2 figures.)

E. M. Blake.

Klauder, J. V., and Dublin, G. J. **Syphilitic uveitis.** *Arch. of Ophth.*, 1946, v. 35, April, pp. 384-399.

This detailed article thoroughly discusses factors in diagnosis and treatment of this disease.

Syphilitic uveitis characteristically occurs in the secondary or late secondary stage of syphilis. The diagnosis is not difficult in patients in whom there is clinical evidence of early syphilis, a positive Wassermann reaction and prompt retrogression of the ocular inflammation after antisyphilitic treatment. The Herxheimer reaction in the uveal tract is described after arsenical and after penicillin therapy. This reaction was observed in 70 percent of the patients. The Herxheimer reaction is discussed from the standpoints of its diagnostic importance and from possible harm that might result from the reaction. Seventy-two cases of syphilitic uveitis are reported and the response to treatment studied. Prompt improvement occurred in patients

given chemotherapy. There was no special advantage noted in the use of fever therapy except as an initial treatment for very severe processes. In patients of this type initial reduced doses of a bismuth compound prior to injection of an arsenical serve the same purpose. Penicillin was used exclusively in seventeen patients with good results. (References.) John C. Long.

Lachman, R., and Pérez Chacón, E. Cured bilateral endogenous uveitis. *Rev. Oto-Neuro-Oft.*, 1946, v. 21, May-June, pp. 61-63.

An acute bilateral uveitis with miosis and hypopyon in the right eye developed in an individual with bronchopulmonary disease. He was given penicillin and atropine. The hypopyon disappeared in two to three days, but the miosis persisted. To help overcome this, ephedralin was injected subconjunctivally near the limbus of each eye in the 12-, 3-, 6-, and 9-o'clock positions. This resulted first in irregular mydriasis, and an improved visual acuity. Within a day both pupils were dilated uniformly. On the ninth day of treatment penicillin was stopped. After two weeks vision had improved from light perception to 10/10. (Bibliography.)

Laval, Joseph. Spontaneous cyst of the iris. *Amer. Jour. Ophth.*, 1947, v. 30, Jan., pp. 55-57. (2 figures.)

Legroux. A case of sympathetic neuropapillitis. *Arch. d'Opht.*, 1946, v. 6, no. 1, pp. 43-45.

The author presents the case of a boy, 15 years of age, who developed sympathetic ophthalmia, limited to the posterior segment, 22 days after a foreign body penetrated and destroyed

the sight of the inciting eye. When first seen the vision of the sympathizing eye was 1/10 and a central scotoma was present. Fundus examination revealed an optic neuritis; there were no signs of iris or ciliary body involvement. Enucleation of the inciting eye was performed immediately. A daily dose of six grams of Rubiazol was given for six days. The visual acuity began to rise after the second day and in three weeks had become 6/10. At the same time, however, the edema of the optic nerve and retina increased and at the end of another month the vision had fallen back to 2/10. In addition to a central scotoma, peripheral field constriction developed. Treatment in the following weeks consisted in trepanation of the right sphenoid sinus, a second course of sulfonamides, and finally a course of sodium salicylate. By the end of the ninth month the visual fields had become normal and vision remained stationary at 4.5/10. The fundus had returned to normal except for a slight blurring of the disc margin. The author makes a plea for prophylactic removal of badly damaged eyes.

Phillips Thygeson.

Levine, M., and Gordon, M. Ocular tumors with exophthalmia in xiphophorine fishes. *Cancer Research*, 1946, v. 6, April, p. 197.

The authors report that in four of 500 aquaria (all under the same dietary and environmental influence) they found xiphophorine (swordtail) fishes who showed unilateral or bilateral exophthalmos. Histopathologic study revealed a malignant choroid tumor composed predominantly of epithelioid cells, that resembled the malignant melanomas of the human eye. The etiology of these tumors is unknown,

and their occurrence cannot be explained genetically in Mendelian terms.
Benjamin Milder.

Lijo Pavia, J., and Lachman, R. **Congenital aniridia. Three observations.** *Rev. Asoc. med. Argent.*, 1946, v. 60, April, pp. 179-181.

The authors report three cases of aniridia. The first patient had a total bilateral aniridia associated with zonular opacities and posterior polar cataract in the left eye; the second had an incomplete bilateral aniridia associated with pseudoptosis; and the last an incomplete congenital unilateral aniridia associated with a pseudoptosis. (2 pictures and a brief bibliography.)

Jose Saenz Canales.

McArevey, J. B. **Sympathetic ophthalmitis.** *Trans. Ophth. Soc. U. Kingdom*, 1944, v. 64, pp. 300-304.

The author emphasizes that operations on secondary cataracts should be avoided. A careful preoperative examination of all eyes with the slitlamp will discover a low grade uveitis. He recommends the removal of an injured eye which suddenly shows fine bedewing of the posterior endothelium or when the clinical appearance of continued irritation persists despite treatment.

During the year 1943 at the Royal Victoria Eye & Ear Hospital, Dublin, 50 eyes were removed after perforating injuries, 20 were examined and in 12 of these sympathetic disease was present. In two patients the second eye had become affected. The shortest intervals of time between injury and enucleation in 10 cases of sympathetic ophthalmia were 9, 12, 17 and 21 days and two of the patients had had injuries for two years before the eyes were enucleated.

Beulah Cushman.

Meesman, A. **A contribution to the pathogenesis of postoperative choroidal detachment.** *Revue Bulgare d'Opht.*, 1943, v. 2, pp. 137-150.

The origin of the postoperative choroidal detachment is discussed.

The author's own experiments consisted of ligations of the vortex veins in rabbits to determine whether a stagnation hyperemia in the choroid with normal or subnormal tension could cause a choroidal detachment. The dilatation of the uveal vessels was considerable but the vitreous did not yield, or shrink, or shift towards the anterior parts of the eye. A choroidal detachment only occurred after paracentesis with a resulting advancement of the iris-lens-diaphragm.

Alice R. Deutsch.

Mosquera, Sanchez. **The separation of iridocapsulary synechia.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1945, v. 5, Sept., p. 806.

The author emphasizes the value of massage in the separation of fresh synechiae which are resistant to the instillation of a mydriatic.

Ray K. Daily.

Picena, J. P., and Paez Allende, F. **Achromic choroidal melanoma.** *Anales Argentinos de Oft.*, 1946, v. 7, April-May-June, pp. 39-47.

Although the great majority of choroidal sarcomas are melanotic, occasionally a leucosarcoma is observed. An 80-year-old woman had a pale gray tumor at the posterior pole of the right eye. Acute glaucoma supervened and necessitated enucleation. Histologic study of the eye revealed neoplastic sarcomatous tissue with rosettes, and special staining showed the presence of melanoblasts. (Bibliography.)

Edward Saskin.

Reed, H. Etiology of iridocyclitis in the African. *Brit. Jour. Ophth.*, 1946, v. 30, June, pp. 324-337.

In Lake Province, Tanganyika Territory of Africa, 42 cases of iridocyclitis were seen. Only 28 patients could be kept in the hospital for complete study. Except for slitlamp examination and some elaborate laboratory studies the investigation was complete. The study was materially hampered by the general preference for the witch doctor's regimen. There were 20 positive Kahn reactions, 8 patients had gonorrhea, 3 relapsing fever, 10 dental sepsis, 9 malaria, 9 schistosomiasis, 8 ankylostomiasis, and 2 taeniasis. The author concludes that the incidence of iridocyclitis in a tropical community is an index of the extent to which it is disease-ridden.

Morris Kaplan.

Rubino, A., and Corazza, G. Uveomeningitic syndrome. *Riv. Oto-Neuro-Oft.*, 1941, v. 18, no. 3, pp. 177-198.

The authors describe the first case of Harada's disease observed in Italy. A benign lymphocytic meningitis was accompanied by a very severe uveitis, which reduced visual acuity of both eyes to finger counting. Two months later, the retinas were reattached, and large areas of depigmentation were found in both fundi surrounding the discs which again had an almost normal appearance. Slight increase of intraocular pressure was due to remnants of synechiae; final vision was 0.3 and 0.2 respectively. A filterable virus was assumed to be responsible for both the meningeal and the uveal lesions.

K. W. Ascher.

von Sallmann, L., and Di Grandi, J. Hydrogen ion concentration of the aqueous. *Arch. of Ophth.*, 1946, v. 35, June, pp. 643-654.

A capillary glass electrode was designed to determine the hydrogen ion concentration of the aqueous of rabbits in vitro and in vivo. This technique eliminated many of the errors present in earlier methods. The observers found that the average physiologic pH of the rabbit aqueous was 7.53 with brief local anesthesia and between 7.44 and 7.49 in the initial stage of systemic anesthesia. Exogenous infections of the vitreous with *Staphylococcus aureus* caused a moderate shift of the hydrogen ion concentration of the aqueous to the acid side. A diet rich in alkali, an increase in the protein of the aqueous, and the iontophoretic introduction of anions had no noticeable effect on the pH of the aqueous. (References.)

John C. Long.

Sorsby, A. and Gormaz, A. Iritis in rheumatic affections. *Brit. M. J.*, 1946, April 20, pp. 597-600.

In an attempt to assess the frequency of iritis in the rheumatic affections, 815 patients suffering from the various forms of rheumatism were examined for evidence of active or past iritis and compared with those of a control series. Iritis was observed in 3 of 123 patients with osteoarthritis, in 3 of 53 patients with ankylosing spondylitis in 15 of 332 patients with rheumatoid arthritis and never in 313 patients with other forms of rheumatoid disease. The iritis in rheumatoid arthritis was usually mild, unilateral and recurrent. The inflammatory reactions in the eye and the joint are similar in that they are both ascribed to indirect bacterial activity. The literature is reviewed. It shows little appreciation of the frequency of iritis in rheumatoid arthritis. (References.)

I. E. Gaynon.

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
904 Carew Tower, Cincinnati 2

News items should reach the editor by the 12th of the month

DEATHS

Dr. Robert Gewanter, Long Island City, New York, died November 10, 1946, aged 44 years.

Dr. Matthew Gerard Golden, Brooklyn, New York, died November 11, 1946, aged 52 years.

Dr. Carl Miller Sneed, Columbia, Missouri, died November 6, 1946, aged 69 years.

MISCELLANEOUS

BOOKS AND WORLD RECOVERY

The desperate and continued need for American publications to serve as tools of physical and intellectual reconstruction abroad has been made vividly apparent by appeals from scholars in many lands. The American Book Center for War Devastated Libraries has been urged to continue meeting this need at least through 1947. The Book Center is therefore making a renewed appeal for American books and periodicals—for technical and scholarly books and periodicals in all fields and particularly for publications of the past ten years. We shall especially welcome complete or incomplete files of the *American Journal of Ophthalmology*.

The generous support which has been given to the Book Center has made it possible to ship more than 700,000 volumes abroad in the past year. It is hoped to double this amount before the Book Center closes. The books and periodicals which your personal or institutional library can spare are urgently needed and will help in the reconstruction which must preface world understanding and peace.

Ship your contributions to the American Book Center, c/o The Library of Congress, Washington 25, D.C. freight prepaid, or write to the Center for further information.

SOCIETIES

MEMBERSHIP THESIS

At the February 25th meeting of the Milwaukee Oto-Ophthalmic Society, Dr. George Dunker presented his thesis for membership. His subject was, "Report on a Series of 18 Cases of Acute Infectious Pseudomembranous Diplobacillary Conjunctivitis."

WILMER RESIDENTS ASSOCIATION

The sixth annual meeting of the Wilmer Institute Residents Association was held at

the Johns Hopkins Hospital in Baltimore, April 17th to 19th.

PAN-AMERICAN CONGRESS

Those who expect to attend the Pan-American Congress in Havana January 4 through January 10, 1948, should send their names to Dr. Tomas R. Yanes, P.O. Box 970, Havana, Cuba. The Sociedad Cubana de Oftalmologia has ratified the powers conferred in Montevideo upon Dr. Yanes, who will act as president of the local committee, assisted by members of the Cuban society.

SOUTHWESTERN MEDICAL FOUNDATION

The Southwestern Medical Foundation gave a dinner at Dallas, Texas, on February 28th in honor of Dr. Edward Henry Cary on the anniversary of his 75th birthday.

ATOMIC ENERGY IN MEDICINE

At the February meeting of the Reading Eye, Ear, Nose, and Throat Society held jointly with the Diplomates Association of Berks County Physicians, Dr. Eugene P. Pendergrass spoke on "Atomic Energy in Medicine."

HOLLAND PHYSICIAN SPEAKS

At the January meeting of the Cleveland Ophthalmological Club, Dr. John A. Van Heuven of Utrecht, Holland, was the guest speaker. He gave a most enlightening and interesting paper on "Retinal Detachment." Following his formal paper, Dr. Van Heuven spoke informally on his experiences with the medical division of the underground in Holland.

ANNOUNCEMENTS

HOME STUDY COURSES

The Home Study Courses, sponsored by the American Academy of Ophthalmology and Otolaryngology, in the basic sciences of those two specialties, will be given again, beginning September 1, 1947. Registrations must be completed before August 15th. Detailed information may be obtained from Dr. William L. Benedict, executive secretary, 100 First Avenue Building, Rochester, Minnesota.

OPTICAL AIDS FOR SUBNORMAL VISION

The Committee on Sensory Devices of the National Research Council has available a limited number of reprints of a condensation

of a "Report on a Survey of Optical Aids for Subnormal Vision," by V. S. Ellerbrock, recently published in the *Journal of the Optical Society of America*. There are also available a limited number of copies of the original unabridged report. This report, which was prepared to guide the committee in formulating a program of research, deals with the theory and practical aspects of telescopic spectacles, loupes, reading-glass magnifiers, and projection systems, as well as with recommendations for possible improvements in these devices. Copies of either of these reports will be mailed to professionally interested persons on request to the: Dartmouth Eye Institute, 4 Webster Avenue, Hanover, New Hampshire.

WILDER MEMORIAL LECTURE

Dr. John Q. Griffith, Jr., Laboratory for the Study of Hypertension, Philadelphia, will deliver the third William Hamlin Wilder Memorial Lecture of the Institute of Medicine of Chicago on Friday evening, May 23rd, at the Palmer House. His subject will be, "Rutin: A Therapy for the Hemorrhagic Complications of Hypertension."

EXAMINATIONS FOR TECHNICIANS

The next examination by the American Orthoptic Council will be held in September-October, 1947.

The written examinations will be held at

various cities in the country on Friday, September 12, 1947. Only those passing the written examinations will be permitted to take the oral and practical tests, to be given in Chicago, Saturday, October 11, 1947.

Applications on official forms must be received before July 1, 1947. Address the American Orthoptic Council, 23 East 79th Street, New York 21, New York.

PERSONALS

Dr. Franklin M. Foote, New York, has been named medical director of the National Society for the Prevention of Blindness. Dr. Foote formerly was chief of the Division of Local Health Administration, Connecticut State Department of Health, and is now assistant professor of Public Health in Preventive Medicine, Cornell University Medical College.

Leon S. Stone, Ph.D., Bronson professor of Comparative Anatomy, Yale University School of Medicine, New Haven, will receive the Robert W. Doyne Memorial Medal, an annual award of the Oxford Ophthalmological Congress in England. Dr. Stone, who will go to England next summer to address the Congress at Keble College, Oxford, was given the award in recognition of his work on retinal regeneration and vision experiments in transplanted eyes.

Erratum

On page 282 of the March, 1947, issue of the JOURNAL, in the first column, last line of the first paragraph, "45 to 50 mm. wide" should read "45 to 50 μ wide."

PIGMENTED TUMORS*

THE DE SCHWEINITZ LECTURE

ALGERNON B. REESE, M.D.

New York

GENERAL CONSIDERATIONS

Cells that produce pigment are called melanoblasts, and the pigment they produce is called melanin. Actually, we know very little about these cells and their product. For this reason, there is great difference of opinion regarding them, and those who are close to the subject and have given it a great deal of thought are reluctant to express definite concepts. Knowing full well that the whole subject is in a state of flux, and having already qualified myself to speak freely on the ground that those who know most about it will not, I shall attempt to outline the frontiers of the subject as I see them on the basis of our present knowledge. My approach will be from the neoplastic standpoint, and in this regard ophthalmologists have a great deal at stake, for their work embraces every type of pigment-bearing tumor.

The term "melanin" is a general non-specific one applied to almost any black, brown to tan pigment. It probably includes a heterogeneous group of pigments which have the common characteristic of absorbing visible light in a somewhat uniform manner.

Morphologically the melanin pigments encountered in the eye differ. That seen in the pigment epithelium of the retina is black and composed of discrete rods, while that in the chromatoblasts of the uvea is light and appears as varying-sized, amorphous, crystalline granules. It is quite possible that it will be shown some day that the melanins produced by various types of melanoblasts differ chemically, in staining reactions, in spectral absorption, or in other ways.

It has been established, mainly through the work of Bloch,¹ that melanoblasts contain an oxidase which is specific for oxidizing "dopa" into a substance resembling melanin. According to Laidlaw,² this oxidase is increased wherever melanin is being produced and is the invariable precursor of melanin. Where there is no melanin produced there is no oxidase, and where there is no oxidase no melanin is produced. The oxidase appears first and melanin next and the order is never reversed. The oxidase appears in the cell sometimes before the resultant melanin is visible, and the melanin itself may remain in the cell long after the oxidase has disappeared. As Bloch³ has pointed out, the cells around the growing margin of a malignant melanoma are more apt to contain the oxidase than those in the supposedly less-active cells in the center.

It appears, therefore, that access to this oxidase is essential for a cell to fabricate

*Delivered before the Section on Ophthalmology of the College of Physicians, Philadelphia, November 21, 1946. From the Institute of Ophthalmology of the Presbyterian Hospital, New York City, and the Memorial Hospital for the Treatment of Cancer and Allied Diseases, New York City.

melanin. It is not known whether or not the oxidase is found in the cell itself or comes from some source outside of the cell, or whether or not it acts upon the cell causing the cell to synthesize melanin, or merely promotes the conversion of a leukomelanin or premelanin substance in the protoplasm to melanin. It seems, however, that, when this oxidase is available, many cells have the potentialities of showing melanin in their protoplasm.

Sometimes a malignant melanoma is associated with generalized melanosis in which pigment is seen in the connective tissue and reticulo-endothelial cells and, rarely, everywhere over the body including the endothelium of blood vessels, and even in the parenchymal cells of organs such as the kidney and the thyroid. The question of whether this is a result of phagocytosis of pigment dispersed from the primary site of the tumor must be considered, but it seems probable in some instances that the cells have stepped out of their usual role and become true melanoblasts. Time may prove, therefore, that any cell can fabricate melanin in its protoplasm if the necessary ferment is available, and that certain cells are usually melanoblasts because this ferment is available. Its availability may evolve around the peripheral sensory nerves.

The fact that this oxidase is available and even elaborated by a pigment-producing growth leads to changes in the tissues which may be confusing both histologically and clinically. Histologically, the cells composing the tissue harboring the tumor may be converted into melanoblasts, thus clouding the histologic picture in that the cells belonging to the tumor proper may be confused with those cells belonging to the stromal elements or to the host tissue. Clinically, the elaboration of oxidase by the tumor may be significant because it serves to explain the melanosis of the tissue adjacent to the

tumor or of the tissues which come into contact with the tumor. Clinical observations which bear this out are the following:

1. A nevus of the caruncle may give rise to a melanosis of the skin covering the adjacent canaliculi which come in contact with the tumor surface. Aside from the melanosis the skin is normal in appearance.
2. The conjunctiva adjacent to a nevus may show the melanosis and no other appreciable change. This may also be true of the corneal epithelium adjacent to a nevus of the limbus.
3. In an actively growing malignant melanoma of the skin or conjunctiva, the pigment halo of the adjacent skin or conjunctiva is not uncommon.
4. The café-au-lait pigmentation of the skin over the site of neurofibromatosis is a pigmentation of the basal layer of an otherwise normal skin.
5. When a nevus involves the lid margin, there may be a melanosis and even an epithelial hypertrophy of the margin of the other lid at the site where the nevus comes in contact with it.
6. Benign pigmented lesions sometimes occur on the iris in eyes harboring a malignant melanoma elsewhere in the uvea.

The appreciation of the nature of this melanosis of the tissues adjacent to, or in contact with, a pigmented lesion may assume clinical significance when such lesions are being excised. A simple melanosis, which is secondary to the product elaborated by the neoplasm, does not have to be included in the excision. This is important when the inclusion of such melanosis in the excision entails extensive plastic repairs and the sacrifice of important structures.

The process of oxidation is responsible for the appearance of melanin in the pro-

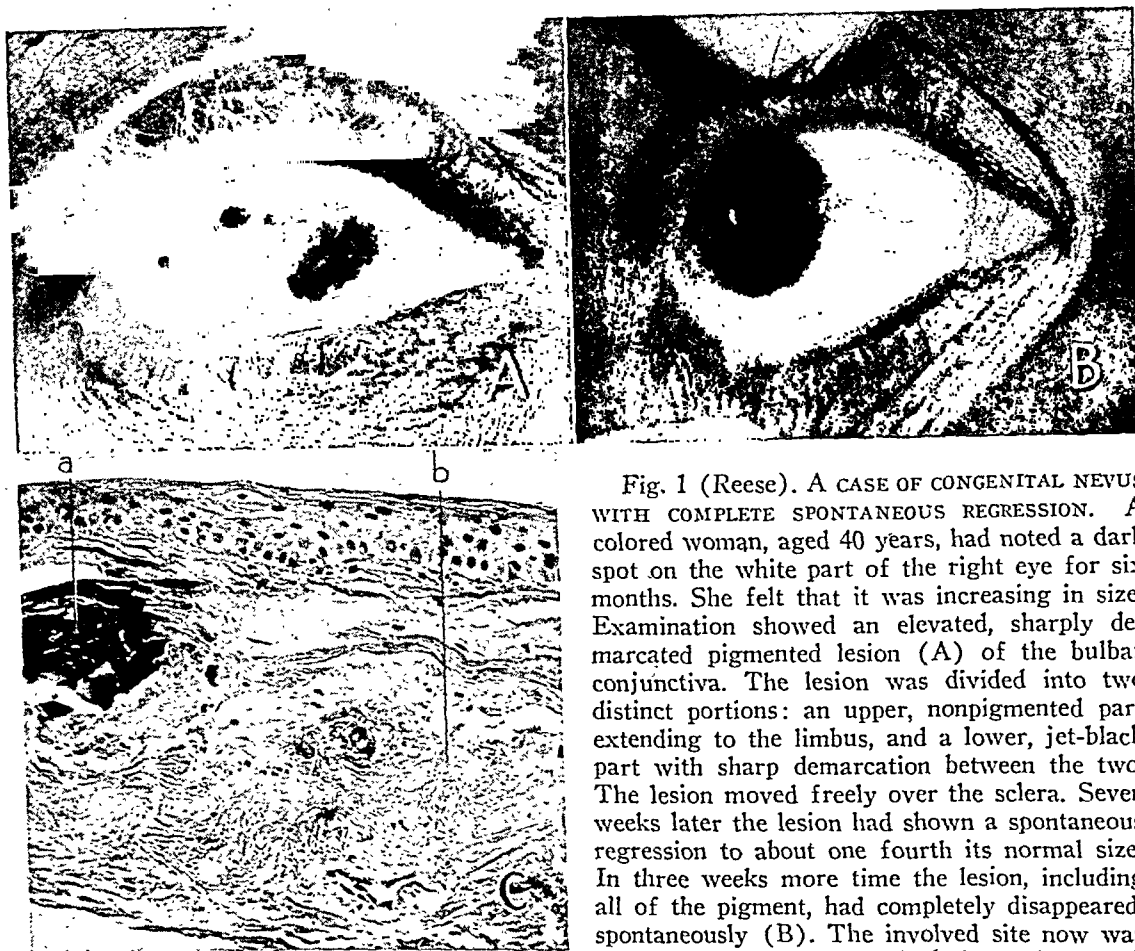

Fig. 1 (Reese). A CASE OF CONGENITAL NEVUS WITH COMPLETE SPONTANEOUS REGRESSION. A colored woman, aged 40 years, had noted a dark spot on the white part of the right eye for six months. She felt that it was increasing in size. Examination showed an elevated, sharply demarcated pigmented lesion (A) of the bulbar conjunctiva. The lesion was divided into two distinct portions: an upper, nonpigmented part extending to the limbus, and a lower, jet-black part with sharp demarcation between the two. The lesion moved freely over the sclera. Seven weeks later the lesion had shown a spontaneous regression to about one fourth its normal size. In three weeks more time the lesion, including all of the pigment, had completely disappeared, spontaneously (B). The involved site now was dull, granular, nonelevated, and nonpigmented.

After two months, no change was noted, and a piece of tissue from the former site of the lesion was removed for biopsy (C). Under the conjunctiva is a structureless, amorphous, degenerated tissue with no visible nuclei. At (a) and (b) there is coagulation necrosis with calcium deposition in (a). This tissue showed negative reaction to stains for hyalin. No trace of pigment or nevus cells. (Hematoxylin and eosin stain.) This was a congenital, nonpigmented nevus which suddenly became partially pigmented and later went on to complete and spontaneous regression.

toplasm of a melanoblast. This seems to convert a preëxisting premelanin or melanogenic substance in the protoplasm into black, visible melanin. It probably does not cause the melanin to be produced by metabolism of the cell protoplasm. The oxidation of this preëxisting leukomelanin into black melanin takes place rapidly and is reversible; that is, after the melanin has been formed, it can be reduced to the invisible premelanin. Clinically, we may see the pigment content of a nevus increase rapidly and this change is frequently mistaken for active growth. Also, the pigment content of

a nevus may decrease and, in fact, the entire nevus may disappear spontaneously and completely (fig. 1). Also, acquired spontaneous precancerous melanosis may appear, regress, and reappear (fig. 2). This fluctuation in the pigment content is contingent on the process of oxidation and reduction.

There is evidence of a hormonal influence in pigmentation in animals and man. The sex hormones in particular are implicated as shown by many workers including Willier⁴ using the color pattern in the plumage of birds and Gordon⁵ using fishes, as their media. Hamilton⁶

Fig. 2 (Reese). A CASE OF PRECANCEROUS MELANOSIS WITH SPONTANEOUS REGRESSION AND REAPPEARANCE. A woman, aged 45 years, noticed what she thought was a hemorrhage the size of a pinhead on the white part of the right eye in 1931. This gradually enlarged. She was observed first in February, 1938, at which time there was a nonelevated, pigmented lesion of the bulbar conjunctiva temporally adjacent to the limbus, measuring 5 by 5 mm. and encroaching for 1 mm. on the cornea. There was a diffuse, fine, granular pigmentation of the bulbar conjunctiva nasally. The patient was observed elsewhere from time to time until December, 1938, when it was noted that the lesion measured 7 by 7 mm. with no apparent increase in the granular pigmentation nasally. In April, 1939, it was observed that the lesion had regressed. The regression occurred spontaneously as there had been no treatment. The drawing above shows consecutive sketches drawn to scale. Some of these were used in a previous article.¹⁰ The fine, granular pigmentation of the bulbar conjunctiva nasally also disappeared. In May, 1941, no actual recurrence was seen, but there was noted with the slitlamp a fine, granular pigmentation at the site of the former lesion and for some distance around it. In May, 1942, in addition to the pigment shown in the sketch, there was also noted again a slight diffuse pigmentation of the bulbar conjunctiva nasally.

In addition to the ocular findings, there were pigmented lesions elsewhere which were undergoing changes. In April, 1939, a pigmented lesion on the right cheek of unknown duration disappeared spontaneously, leaving a slightly elevated, non-pigmented area, with an uneven surface, measuring 5 by 3 mm. In May, 1941, there was a slightly brownish papule in the right periauricular region, measuring 4 mm. in diameter, of three months duration. In October, 1941, this lesion had disappeared.

and others have studied the pigment deficiencies of eunuchs. Pack⁷ has never encountered a malignant melanoma in human beings before puberty but feels that they are particularly prone to occur, and to be unusually malignant at the time of puberty. The pigment in the skin, in congenital nevi, and in the iris also manifests itself more markedly at puberty. A melanoma is more malignant when it occurs during pregnancy at which time there is also other evidence of pigment activity, as exemplified in the usual increase in the pigmentation of the areola of the breasts and vulva.

There is not much evidence that genetics and heredity play a very important role in pigmented tumors. There are a few instances, however, in which a

definite familial tendency was observed in the incidence of malignant melanoma of the uvea. The most noteworthy is that cited by Davenport⁸ of five cases in three generations of one family. I have seen two sisters with a malignant melanoma of the ciliary body. Gordon⁹ has demonstrated the significance of genetics and heredity in the transmissibility of melanoma in fishes.

Free melanin is liberated from the protoplasm of melanoblasts of the skin and conjunctiva both as a constant physiologic occurrence and as a response to some provoking factors, such as actinic rays, neoplasms, and hyperpigmented states. The melanin particles are either absorbed and may be detected in the urine and the lymph nodes, or they may be phagocy-

tosed by the histiocytes of the derma or submucosa. The cells that take on, and merely harbor melanin made by other cells are called melanophores or chromatophores.

TYPES OF MELANOBLASTS

I have given this preliminary discussion of melanoblasts and melanin in general, and my efforts will now be directed toward presenting histologic and clinical evidence in favor of the existence of various types of melanoblasts from which stem various types of tumors. The subject is still highly speculative but there does seem to be sufficient evidence to warrant using the following outline for the purpose of this discussion.

NEUROGENIC MELANOBLAST

A. Schwann cell

Location: all peripheral nerves

B. Nevus cell

Location: peripheral sensory nerve terminals

C. Melanoblasts stemming from secondary optic vesicle

Outer layer—

1. Location: pigment epithelium of the retina and ciliary body (fig. 3-A, B)

2. Location: dilator and sphincter muscles of iris (fig. 3-C)

Inner layer—

Location: pigment epithelium of iris (retinal epithelium of iris) (fig. 3-D)

D. Lepto-meninges (pia)

Location: brain and optic nerve

ECTODERMAN MELANOBLAST

Location: basal layer of the skin and mucous membranes

MESODERMAL MELANOBLAST

Location: uvea, sacral and extra-sacral mongol spot

NEUROGENIC MELANOBLASTS

A. SCHWANN CELL

A fibrous syncytium of Schwann cells sheathes all peripheral nerves immediately upon their exit from the central nervous system. Normally the Schwann cell does not produce pigment, but in pathologic states this cell becomes very versatile and may not only produce melanin but also, according to Masson and Martin,¹⁰ a metaplastic striated muscle; according to Wilson,¹¹ bone; and accord-

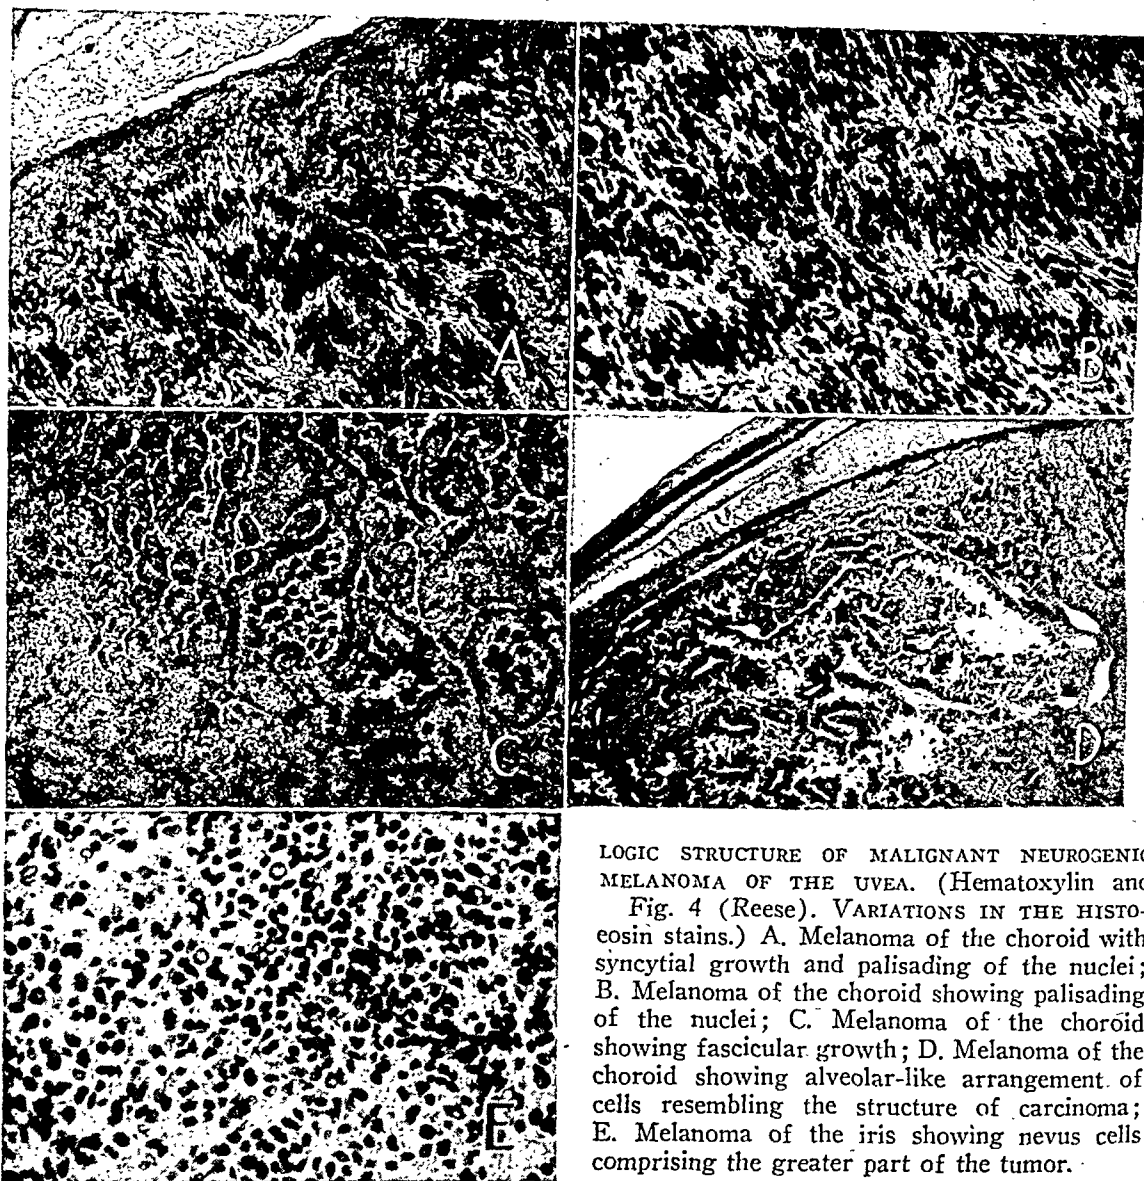

Fig. 3 (Reese). SECONDARY OPTIC VESICLE. A. Anlage of pigment epithelium of retina; B. Anlage of pigment epithelium of ciliary body; C. Anlage of dilator and sphincter muscles of iris; D. Anlage of pigment epithelium of iris (retinal epithelium of iris).

ing to Groth,¹² cartilage and fat. Moreover, it becomes modified at the sensory nerve terminals to form various manifestations of end-organs, including the Meissner corpuscle, the Pacinian body, and the tactile cell of Merkel and Ranvier.

A tumor arising from this cell along the trunk of a nerve usually contains no pigment, is encapsulated, and is benign. In ophthalmology it is more often seen in the orbit and is called a neurinoma or neurilemmoma. A tumor arising from this cell at the sensory nerve terminals or near these nerve terminals is usually associated with the production of pigment, is

LOGIC STRUCTURE OF MALIGNANT NEUROGENIC MELANOMA OF THE UVEA. (Hematoxylin and

Fig. 4 (Reese). VARIATIONS IN THE HISTO- eosin stains.) A. Melanoma of the choroid with syncytial growth and palisading of the nuclei; B. Melanoma of the choroid showing palisading of the nuclei; C. Melanoma of the choroid showing fascicular growth; D. Melanoma of the choroid showing alveolar-like arrangement of cells resembling the structure of carcinoma; E. Melanoma of the iris showing nevus cells comprising the greater part of the tumor.

frequently called a nevus or a melanoma, and may be quite malignant. A tumor arising from both the nerve trunk and the sensory terminals, and being, therefore, a diffuse lesion, is usually called neurofibromatosis and this type of lesion is also associated with the production of pigment. According to Stout,¹³ 20 per cent of neurofibromas become malignant.

A benign or a malignant melanoma of the uvea may also arise from the Schwann cell. This idea was first advanced by Theobald¹⁴ who presented specimens showing nerves fanning out into the tumor tissue indicating that the neoplasm arose from the Schwann sheath.

She also pointed out the occurrence of benign pigmented lesions associated with the ciliary nerves.

Further evidence supporting the neuralistic postulate of some melanomas of the uvea is the following:

1. The histologic structure of some of the uveal melanomas is consistent with that of the neurinoma which appears elsewhere. This is particularly true in regard to the syncytial fascicular type of growth and the palisading of the nuclei (fig. 4-A, B, C).

2. The short, as well as the long, ciliary nerves on the side of the globe harboring the melanoma may show enlargement due

Fig. 5 (Reese). A MALIGNANT NEUROGENIC MELANOMA of the iris (a) with enlargement of the long ciliary nerve seen at (b), (b¹), (b²), and (b³). At (c) an intrascleral nerve loop extends off of the main branch. At (d) there are cystic spaces in the tumor. The nerve at (b) and (b¹) is 3 to 4 times the size of the same nerve to the opposite side of the optic nerve. (Hematoxylin and eosin stains.)

to overgrowth of the Schwannian element (fig. 5). A similar enlargement of the ciliary nerves, but to a greater extent, may be seen in cases of neurofibromatosis involving the trigeminal area but not the orbit directly. In such instances benign pigmented lesions may be present in the uvea.

3. A ciliary nerve coursing toward the site of a melanoma of the uvea may show single or multiple benign melanomatous growths composed of Schwann cells (fig. 6-A, B).

4. Typical nevus cells may be seen at sites in a uveal melanoma and in some instances, particularly when the lesion is located in the iris or ciliary body, the entire tumor may be composed of nevus cells (fig. 4-E).

5. There are reports in which the eye affected with a malignant melanoma

showed an anesthesia of the cornea (Sédan, 1934¹⁵) and an alteration in the size and reaction of the pupil (Philippsen, 1891¹⁶).

6. In amphibia and fowls when a portion of the neural crest is transplanted, the site of the transplantation on the host takes on pigment characteristics of the donor. It has been shown by Willier¹⁷ in fowls that melanoblasts migrate out from the neural crest into the mesoderm and that these cells determine the pigment pattern of the animal. Grafts transplanted before these neurectodermal melanoblasts have migrated into the mesoderm show no pigment changes in the host and those transplanted after the migration show the pigment pattern of the donor animal. This would indicate that neurectodermal melanoblasts can appear far and wide from their anlage, and sug-

Fig. 6 (Reese). A MALIGNANT NEUROGENIC MELANOMA of the iris with a benign neurogenic melanoma of the long ciliary nerve. A. A diffuse malignant neurogenic melanoma of the iris; B. The long ciliary nerve (a) coursing toward the tumor shows a large fusiform pigmented enlargement (b'), (b''), (b'''), due to overgrowth of the Schwannian cells (benign neurogenic melanoma); C. A high power of (B) at (a) showing long ciliary nerve (a) with its fusiform pigmented overgrowth of Schwannian cells (b')-(b'').

gests the possibility that melanoblasts most anywhere could stem from the neurectoderm.

7. Cases reported in ophthalmic literature supporting the neurogenic thesis are the following:

- a. Strachov¹⁸ reported a case showing general manifestations of Recklinghausen's disease, neurinoma of the right orbit, and a malignant melanoma of the choroid of the left eye.
- b. Gartner¹⁹ reported a case of malignant melanoma of the choroid with multiple skin nodules which proved to be manifestations of Recklinghausen's disease. He also cited three other cases in the literature in which the two conditions were associated.
- c. Moorhouse²⁰ reported a tumor of the choroid which resembled a malignant melanoma but was diagnosed microscopically a neurofibroma. He claimed that a subsequent general examination established a diagnosis of Recklinghausen's disease.

Theobald's¹⁴ contention that melanomas of the uvea may be neurogenic is well documented and there seems no reason to doubt that such tumors may arise from Schwann cells. Judging by the behavior of tumors elsewhere which arise from Schwann cells or allied cells, one must presume that the nearer the tumor is to the nerve-trunk type of lesion (neurinoma) the more benign it is, and the nearer it is to the peripheral-nerve type of lesion (melanoma) the more malignant it is.

I²¹ called attention to the frequency of benign melanomas of the iris in eyes harboring a malignant uveal melanoma. It seems probable that these multiple manifestations occurred in neurogenic melanomas because diffuseness and multiple sites are common occurrences in neoplastic lesions of the Schwann cell.

B. NEVUS CELL

To discuss the nature of the nevus is to discuss Masson's contributions²² on the subject, so completely has his work dominated the picture. However, interpretation of his teachings varies among his disciples. It is conceded generally that the nevus is neurogenic and that it takes origin from the sensory nerve terminals, but, beyond this, speculation is rife regarding the more exact nature of the nevus cell. The Merkel-Ranvier tactile cell is most frequently implicated.

Most of the work on the Merkel-Ranvier cell has been done on lower mammals, and surprisingly little information exists regarding these cells in the human being. Perez,²³ Ebert,²⁴ and others by special silver stains describe in the human skin a complex terminal arborization of nerve fibers at the dermo-epidermal junction. Expansions of these nerve terminals were noted around the lower pole of cells scattered at irregular intervals in the basal layer or the layer adjacent to it and these cells were larger and clearer than the neighboring cells. This cell type, together with its terminal nerve meniscus, constitutes the tactile cell of Merkel and Ranvier.

Masson²² describes his "cellule claire" (fig. 7) as occurring at irregular intervals along the junction of the epidermis and the cutis. These cells differ from adjacent cells in their larger, irregular, kidney-shaped nucleus which is denser in chromatin. The long axis of the nucleus is often parallel to the junction of the epidermis and the cutis. Cytoplasmic projections extend into the neighboring intercellular spaces and sometimes into the corium (fig. 7-A, B). A well-defined clear space is noted around the cell. He felt that this clear cell is derived from the Schwann cell which migrated into the epidermis in fetal life.

Masson²² feels that the tactile cell of

Merkel-Ranvier is indistinguishable histologically from the clear cell, that they are both functional and morphologic modifications of the same cell strain—the Schwann cell—and that the nevus cell stems from these cells.

Nevus cells, besides growing diffusely in the epidermis and corium, frequently grow in small clusters and nests beneath the epithelium, or are arranged as abor-

Fig. 7 (Reese). A SECTION OF THE SKIN from the palmar surface of the forearm. The clear cells of Masson are seen scattered along the basal layer. At (a) and (b) a clear cell shows its clear cytoplasmic extension between adjacent basal cells. (Trichrome stain.) (This microphotograph was loaned through the kindness of Dr. Pierre Masson.)

tive forms of specialized tactile organs such as Meissner corpuscles and Pacinian bodies. Foot²⁵ believes that the frequent nests of nevus cells can be viewed as caricatures of Meissner corpuscles. In some nevi, and particularly those of the scalp and in neurofibromatosis of the uvea, well-formed and identifiable Meissner corpuscles are seen.

Masson²² has demonstrated that the structure of a nevus is in general as follows—trunks of sensory nerves approach the deeper layers of the derma beneath the site of a nevus; as those

nerves become more superficial they lose their myelin and their Schwann sheath becomes continuous with a syncytium of nevus cells, which bud out along the nerve branches like flowers from a much branched stem; nerve axones can be traced down the center of these branches or “neuroid tubes” and arborize around the nevus cells in the same manner that they do around the tactile cells of Merkel and Ranvier.

The nevus cell is basically a Schwann cell and, therefore, may sheath the terminal branches of the sensory nerves which act as a scaffolding, or appear at the nerve terminal as a modified tactile cell (Merkel-Ranvier, clear cell). Both types may be present in the same tumor, or one or the other may predominate. Thus, we can recognize a superficial and a deep nevus, or a combination of both.

A superficial nevus lies in and just under the epithelium and comes more from the clear cell or Merkel-Ranvier cell. The cells arrange themselves in nests, which, in the deeper portion, are more elongated and columnar around nerve fascicles and, in the superficial portion, are more spheroidal and more closely resemble caricatures of Meissner corpuscles. Pigment formation is more conspicuous.

A deep nevus lies in the derma under the epithelium, arises more from the nerve sheaths and frequently shows an intervening stratum of normal connective tissue between it and the epithelium. The nerve scaffolding with its outgrowths of nevus cells is more pronounced and the tendency to distorted tactile corpuscles is less. The nevus nests have an affinity for the deep hair follicles. A neurofibromatous element is not infrequent and Laidlaw²⁶ has described what he calls the “cable effect” due to fusiform thickening of associated nerves from proliferation of Schwann cells. Pigment formation is less conspicuous.

There may be a combination of the superficial and the deep nevus, with the superficial part in relation to the epithelium and separated from the deep portion by an intervening layer of connective tissue. Foot²⁵ postulates that one might speak of a neurofibroma developing up to the point where the myelin sheath ends in the nerve trunk, and of a neuronevus when the tumor is situated beyond that point, including the end organs of the nerve.

The nevus cell, therefore, is to be viewed as a modified Schwann cell at the site where Schwann cells normally differentiate into various types of sensory end organs. It is a cell which in its metamorphosis lies between the Schwann cell and the fully differentiated end-organ cell. It is thus not surprising to find sometimes in nevi all morphologic stages ranging from the Schwann cell to the fully developed sensory end-organ. The nevus cell in the role of a melanoblast is consistent to the extent that pigment formation is known to be closely associated with the peripheral sensory terminals. Further than this, however, we cannot go except to surmise that perhaps these terminals elaborate an oxidase.

Laidlaw and Murray²⁶ have advanced a very interesting theory regarding the relationship of nevi to the evolution of the hair follicle. In reptiles and amphibia, which are just below the mammals in the phylogenetic scale, we find normally scattered over the body pigmented dots having the microscopic structures of human nevi. For instance, in the alligator there are numerous black dots prominently seen over the smooth white skin of the upper and lower jaws. Each dot is a tactile organ in which a sensory nerve terminates. As the mammal evolved from the reptilian form, the tactile spots disappeared and were replaced by hair follicles which are primarily tactile organs with

color and warmth as secondary functions. In the human being, the association of nevus and hair follicle is not uncommon, and the nerve terminals around the cells composing each are the same. The hairy, pigmented nevus may be viewed as a link or transition between the aforementioned tactile organs of the reptilian type and the hairy tactile organs of the mammalian type. Ribbert²⁷ felt that many lesions in the human being, including pigmented nevi, represented instances of imperfect survival of structures normal in animals lower in the phylogenetic scale.

In ophthalmology, we see nevi of the skin, of the lids and, more commonly, of the conjunctiva and particularly in the region of the limbus and caruncle. Nevi, or at least their matrices, are congenital, but at birth they are usually not seen because they are small and more or less flesh colored. They seem to grow in size somewhat during the first decade of life, and pigmentation takes place between the ages of 4 to 14 years, particularly around puberty. Some of the larger nevi may show pigmentation even in infancy. It is during the period in which pigmentation is acquired that they are usually noticed for the first time. They seem to undergo some regression in later years and rarely disappear spontaneously and completely (fig. 1). Each individual averages about a dozen or more skin nevi with a predilection for the head, neck, and genital regions.

Approximately one third of the conjunctival nevi do not show pigmentation, but are of a pinkish salmon color. There may be a rather rapid change in the pigment content even in adult life so that a formerly nonpigmented tumor becomes pigmented (fig. 1), or a partially pigmented tumor becomes increasingly pigmented. When the pigment occurs in a formerly nonpigmented growth, the patient may give the history of having noted the lesion for the first time (fig.

A

B

Fig. 8 (Reese). A MALIGNANT NEUROGENIC MELANOMA OF THE CONJUNCTIVA WHICH AROSE FROM A CONGENITAL NEVUS

A man, aged 29 years, had a pigment spot on the bulbar conjunctiva of the left eye temporarily ever since he can remember. When inducted into the army five years ago, the lesion was diagnosed as congenital nevus. During the past two years the spot has grown progressively larger and more elevated. Three months ago it was excised.

A. The lesion before excision. The tumor is quite elevated and sharply demarcated with an upper, flatter, and more densely pigmented portion and a lower, more elevated, but less densely pigmented portion. Many large blood vessels course to the lesion.

B. A section from the excised tumor. The cell border of the protoplasm is well demarcated; there is variation in the size of the nuclei with a tendency to multinucleated cells. (Hematoxylin and eosin stains.)

The tumor recurred three months after the excision, and an exenteration of the orbit has been done.

1). When there has been an increase in the pigment content, both the patient and the doctor may mistake this for growth of the tumor. The appearance and disappearance of melanin in these tumors is based

on oxidation and reduction as previously discussed.

There is no doubt that a nevus can develop into a malignant tumor, but such an occurrence is an extreme rarity. When

Fig. 9 (Reese). HYPERPLASIA OF THE PIGMENT EPITHELIUM of the retina into a large tumorlike mass resulting from an old inflammatory process of childhood.

A woman, aged 56 years, had attacks of "sore eyes" about the age of 5 to 6 years. After this the vision was always poor. For five years both eyes were painful and the vision became further reduced with ultimate blindness and severe pain in the left eye requiring enucleation.

Clinical examination of the left eye showed dilatation of the episcleral vessels and a tension of 70 mm. Hg (McLean). There was a corneal pannus which prevented a view of the interior. The right eye was slightly congested; the cornea showed opacities; there were posterior synechiae; and the tension was 38 mm. Hg (McLean).

The above microphotograph is from the left eye and shows marked hyperplasia of the pigment epithelium. At (a) and (a') the hyperplasia still resembles the mother cells but at (b) it takes the form of a tremendous plaque of metaplastic fibrous tissue interspersed with pigment. The complete gliosis and adherent retina is seen at (c) and (c'); and elsewhere in the eye there was some bone formation in old scar tissue.

The cornea showed old, degenerating scar tissue with calcium deposits; there were peripheral anterior synechiae, occlusion of the pupil, and complete glaucomatous cupping of the disc. (Hematoxylin and eosin stains.)

The consensus of those who studied this section, including Dr. F. H. Verhoeff, was that this represented a pure hyperplasia of the pigment epithelium into a tumorlike mass. (It is through the courtesy of the American Registry of Ophthalmic Pathology and Dr. J. C. Johnston of Charlotte, North Carolina, that this specimen is available.)

such a malignant melanoma does arise, it is a localized elevated tumor mass (fig. 8-A).

True nevus cells may constitute a part or the whole of a neurogenic melanoma of the uvea and particularly is this true when the site of the tumor is in the iris or ciliary body (fig. 4-E). The reason no doubt is that sensory-nerve terminals are more frequent in the anterior uvea. The occurrence of true nevus cells in the uvea has never been pointed out. This finding

furnishes a necessary link in establishing the relationship of some uveal melanomas to the neuronevus seen elsewhere.

C. MELANOBLASTS STEMMING FROM THE SECONDARY OPTIC VESICLE

The entire outer layer of the secondary optic vesicle gives rise to melanoblasts. The posterior portion is the anlage of the pigment epithelium of the retina (fig. 3-A); the middle portion, the pigment epithelium of the ciliary body (fig. 3-B);

and the anterior portion, the dilator and sphincter muscles of the iris (fig. 3-C). Only the anterior portion of the inner layer of the vesicle gives rise to melanoblasts—the pigment epithelium of the iris (fig. 3-D).

Outer Layer

1. PIGMENT EPITHELIUM OF THE RETINA AND CILIARY BODY

a. *Tumors arising from the pigment epithelium of the retina.* These cells proliferate on the slightest provocation. When sufficiently provoked by pathologic processes, their hyperplasia may manifest itself in large plaques of tissue having the characteristics either of the mother epithelial cell or of the metaplastic fibrous tissue (fig. 9). It is safe to say that practically all acquired pigmentary changes in the fundus, not of a neoplastic nature, occur as the result of proliferation of this tissue. It is strange, therefore, that neoplasms arising from these cells are among the rarest occurrences in ophthalmology. Pure hyperplasia into tumorlike masses provoked by some chronic pathologic process in the eye is the usual lesion seen (fig. 9), but as an extreme rarity a true neoplasm may arise from this hyperplasia. These hyperplastic and real tumors are usually found coincidentally in eyes removed for other causes. That the neoplasms arising from this tissue may be malignant and metastasize is illustrated by the case reported by Griffith.²⁸ This is a 37-year-old man whose left eye had been blind for several years. Recently this eye became painful and was, therefore, enucleated. In the routine examination of the eye, a tumor arising from the pigment epithelium was found. Seven months later a recurrence in the orbit was noted, and three months later the patient died from metastasis to the liver.

b. *Tumors arising from the pigment epithelium of the ciliary body.* In these

cases (fig. 10) the overlying nonpigmented epithelium, as well as the pigmented epithelium, may participate. These tumors arise under the same circumstances as those of the pigment epithelium of the retina. They are seen in adult eyes which have been blind for many years, often since childhood. In these eyes there is always residuum of an old inflammatory process, such as a cyclitic membrane with bone formation resulting from an old endophthalmitis. The tumor begins after the inflammatory process has run its course, as evidenced by the fact that the tumor cells invade the already formed organized fibrous tissue or bone. Histologic evidence indicates that the tumor unquestionably arises from a pathologic proliferation of the epithelium.

2. DILATOR AND SPHINCTER MUSCLES OF THE IRIS

Tumors arising from this layer are spontaneous neoplasms. They have the clinical characteristics of involving primarily the pupillary area, showing a flat, diffuse type of growth, and frequently producing an ectropion of the pigment epithelium. These tumors are referred to as leiomyomas.

Inner Layer

PIGMENT EPITHELIUM OF THE IRIS (RETINAL EPITHELIUM OF IRIS)

The tumors from this layer also arise from a hyperplasia provoked by an old inflammation. Spontaneous tumors may also arise from the layer. These occur in younger persons and the tumor tissue resembles more or less the embryonic type of retina. They are usually referred to as dictyomas.

D. MELANOBLASTS OF THE LEPTOMENINGES

The pia covering the optic nerve normally contains long, branching melano-

Fig. 10 (Reese). A MELANOADENOCARCINOMA of the ciliary body arising from the pigment epithelium subsequent to an old inflammatory hyperplasia.

A woman, aged 46 years, suffered a penetrating injury to the right eye at the age of 16 years. Following this the vision was decreased and has become gradually worse so that for the past five years the eye has been blind. During the past year the eye has been red off and on and sufficiently painful to warrant enucleation.

Clinical examination showed congestion of the bulbar conjunctival vessels, especially nasally. In the periphery of the iris at the upper nasal quadrant from the 1- to the 4-o'clock positions, there is a cyst, the base of which seems to arise from the ciliary body. The anterior wall is adherent to the cornea in the angle, and the posterior wall rests upon the lens. There is some dense pigmentation of the adjacent iris tissue and dense pigmentation along the anterior capsule of the lens below the cyst. The lens is completely cataractous preventing a view of the interior. Tension is 45 mm. Hg (Schiotz). The left eye was normal.

The above microphotograph is from the enucleated right eye and shows a melanoadenocarcinoma arising from a hyperplasia of the pigment epithelium of the corona ciliaris. The tumor has invaded and largely replaced the ciliary muscle and processes. The tumor extends into the anterior chamber, from the scleral spur (a) to (b), pushing the root of the iris ahead of it, filling the filtration angle and forming two large thin-walled cysts, (c) and (c'). The tumor forms acini and multilocular cysts. In the delicate stroma are small areas of calcification. The nonpigmented epithelium participates to some extent in the tumor. (Hematoxylin and eosin stains.)

This represents a malignant tumor arising from a hyperplasia of the pigment epithelium of the ciliary body subsequent to an old inflammatory process. (It is through the courtesy of the American Registry of Ophthalmic Pathology and Dr. Julian N. Dow of Los Angeles, California, that this specimen is available.)

blasts. The frequency and distribution of these pigmented cells of the lepto-meninges have been studied by Baader.²⁹ Primary malignant melanomas of the lepto-

meninges arise from these cells. Bailey and Bucy³⁰ speak of all tumors arising in the meninges as meningioma with some qualifying prefix. Consequently they use

Fig. 11 (Reese). A frozen perpendicular section of the mucous membrane of the anal region showing the dendritic cells of the basal layer. (Ammonium silver stain.) (The microphotograph was loaned through the kindness of Dr. Pierre Masson.)

the term "melanoblastic meningioma" for what others call a malignant melanoma.

ECTODERMAL MELANOBLASTS

The basal layer of skin and mucous membranes is a site of melanin production. There is not entire agreement as to the nature of the cell or cells in which the melanin is formed. The various cells implicated in this question are the dendritic cell, the Langerhans cell, the clear cell of Masson, the Merkel-Ranvier cell, and the basal cell of the epithelium.

The dendritic cell (fig. 11) is a branching pigmented cell with its nucleus lying in relation to, and at a slightly lower level than, the basal cells and with its cytoplasmic processes ramifying between the overlying epithelial cells and into the underlying corium. When the cell contains no pigment, it is a rather large clear cell with the protoplasmic ramifications indistinctly seen, and this is the cell Masson calls "cellule claire" (fig. 7). Therefore, according to Masson, the dendritic cell and the "cellule claire" are the same cell with different names, depending on the presence or absence of pigment. When

pigmented, the cell may be seen in the natural state particularly when there is less or no pigmentation of the surrounding cells. The cell may be brought out by silver staining, as well as by the dopa reaction which is strongly positive. These cells are increased in number after irradiation and in hyperpigmented states.

Masson³¹ and others regard these dendritic cells as the sole producers of pigment. They believe that through their cytoplasmic processes these dendritic melanoblasts distribute pigment to cells in contact with them (fig. 12) and that all other cells, being the recipients and harbors of pigment, are melanophores. The protoplasmic processes of the dendrites are said to form not only a syncytium but also to extend to the corium and make contact with reticulo-endothelial system and, therefore, indirectly with the vascular endothelium and circulating blood. They, therefore, constitute a communicating cellular net effecting a metabolic exchange between the circulation and the epidermis. From the corium, the dendrites derive substances of the pigment matrix, form melanin, and deliver it through their processes to the epidermal and dermal cells.

The Masson³¹ concept interprets the dendritic melanoblasts as elaborating or excreting melanin in the same way that glandular cells excrete their products and, therefore, should be really considered glandular cells. The protoplasmic processes inoculate or inject the pigment into the cells of the epidermis and derma with which they come in contact (fig. 12).

The dendritic melanoblasts may wear out and cease to function as melanogenic cells. Such cells are probably replaced by a proliferation of the persisting melanoblasts. Masson³¹ surmised that Langerhans' cells are worn-out or eliminated dendritic cells.

In support of their concept, the proponents cite the fact that in vitiligo some

dendritic melanoblasts still remain but lose their dopa-reaction and, therefore, their melanogenic function. In such instances the epidermis and the derma remain colorless. Also, regions sparsely pigmented such as the palms and soles show pigmentation only of the basal cells in contact with protoplasmic processes of the dendritic cells while the basal cells elsewhere are unpigmented.

Opposing this theory of Masson's,^{22, 31} Bloch³² has advanced several arguments:

1. There is a scarcity of histologic evidence.

2. Experimental work has failed to produce evidence that the basal cells have phagocytic properties.

3. The fact that the basal cells contain a pigment-forming ferment giving a positive-dopa reaction is not taken into account.

4. No explanation is given of how pigment is formed in skin containing no, or only a few, dendritic cells.

5. If melanoblastic properties belong only to the dendritic cells, it is difficult to understand why so long a time elapsed before these cells were found in normal human epidermis.

6. No explanation is given as to how marked pigmentation can exist in normal epidermis, as in the areola of the nipple, with no dendritic cells demonstrable; or, how pigmentation can occur in pathologic melanotic structures with no dendritic cells discernible even with the special stains.

Another hypothesis, which to me seems tenable, is that the dendritic cell represents only a morphologic variation from the basal cell. The number of the dendritic cells varies a great deal within a wide range, and all transitional forms, from the typical dendritic cell to the typical basal cell, seem discernible.

There are many observers who believe that the dendritic cell is merely a well-defined functioning state of a normal pig-

Fig. 12 (Reese). A section from the skin of the large toe showing a single dendritic cell distributing its melanin to the basal cells in contact with the dendrites. Elsewhere the epidermis is free of melanoblasts and pigment. (Cajal stain.) (This microphotograph was loaned through the kindness of Dr. Pierre Masson.)

ment-producing basal cell; that is, a melanoblast par excellence. According to Darier,³³ Bloch,³⁴ Miescher,³⁵ Kreibich,³⁶ and others, the basal cell changes its form and becomes the dendritic cell when its pigment-forming function is at its highest, and, according to Kreibich,³⁶ it changes back to its usual state of rest when increased activity subsides.

It is well known that the pigment epithelium of the retina has phototaxic properties exemplified by the protoplasmic extensions which occur between the rods and cones under exposure to light. This has been demonstrated in animals and is supposed to be true in man. I feel, therefore, that this phototaxic property may be an attribute of the basal layer of the epithelium and that the dendritic processes merely represent morphologic alterations in these cells resulting from their phototaxic property. The following is in support of this thesis:

1. It is known that the dendritic cells

increase in number after exposure to irradiation, and Meirowsky³⁷ found that the areas in which these cells have been increased in number by exposure to irradiation later showed a replacement of the dendritic cells by the normal-appearing basal cells. Peck³⁸ showed that in human skin after exposure to Thorium-X approximately 40 percent of all the basal cells were dendritic. He concluded, therefore, that dendritic cells are most likely a functional modification of ordinary basal cells.

2. Pigment in the basal cells is frequently located as a pigment cap at the superficial pole of the cell, that is, the pole toward the light.

3. After exposure to sun, pigment migrates through the epithelium even to the point of more or less depleting the basal layer. Even the skin of cadavers darkens on exposure to ultraviolet light due to the migrating of melanin to more superficial layers (Blum^{39, 40}).

According to Meirowsky,³⁷ the dendritically constructed melanoblast is present even in a state of rest, and its true form manifests itself by the influx of pigment into the preformed protoplasmic channels. The flow of pigment in prescribed protoplasmic channels has been demonstrated in amphibians, reptiles, and fishes, but not in higher animals (Schmidt,^{41, 42} Biedermann⁴³).

The so-called Langerhans' cell is only brought out by gold-chloride staining and is seen as a delicately branching structure in the epidermis, 3 to 5 cell layers from the corium. No nucleus has ever been demonstrated in this structure and, therefore, it is not a cell entity. Contrary to the belief, which has been erroneously propagated in the literature, the structures do not contain pigment and have nothing to do with pigment formation. Langerhans⁴⁴ considered them nervous end-organs. Masson,⁴⁵ Pautrier-Levy,⁴⁶ Caudière,⁴⁷ and Redslob⁴⁸ have added to the confu-

sion by merging into one the structure of Langerhans and the dendritic cell, and calling it "cellules de Langerhans." As previously mentioned, Masson³¹ viewed the structures described by Langerhans as worn-out dendritic cells which have ceased to function as melanogenic cells.

The nature of the Merkel-Ranvier cell has been discussed under "Nevus Cell" but it injects itself into this issue because of its position in relation to the basal layer of the epithelium and because by some it is considered identical to the dendritic cell and the clear cell.

I believe that the basal cells per se of all epithelium are melanoblasts or potential melanoblasts and that from these cells arise pigmented tumors having specific characteristics. The pigmented tumors in which the basal layer of the epithelium participate are:

1. *Precancerous melanosis*. At the average age of from 40 to 50 years, there may appear in the skin of the lids or the conjunctiva or both a nonelevated, diffuse mottled and more or less granular-appearing pigmentation which may remain with little or no change in a precancerous state for from 5 to 20 years before becoming malignant. The interval may be a great deal longer or considerably shorter, and sometimes the melanosis is malignant from the beginning. The pigment in the lesion may regress and recur (fig.2).

2. *Cancerous melanosis* (figs. 13 and 14). This is a malignant lesion which develops from precancerous melanosis. It may be so diffuse as to involve almost all the bulbar and palpebral conjunctiva and adjacent skin and still be entirely flat with no localized tumor mass. This is a very malignant tumor, and sometimes its harmless appearance with no elevation belies its serious character.

Both precancerous and cancerous melanosis histologically stem from the basal layer of the epithelium (fig. 14-B). These basal cells increase in number, be-

A

B

C

D

E

Fig. 13 (Reese). A CASE OF CANCEROUS MELANOSIS DEVELOPING FROM PRECANCEROUS MELANOSIS

A man, aged 50 years, first noticed a pigmented spot about the size of a pin point along the margin of the left lid in 1915. By 1927, it was about the size of a pinhead. There was further enlargement, so that, in 1932, a biopsy was performed; this showed precancerous changes. The lesion steadily progressed and the patient refused treatment. The sketches in A, drawn to scale, show the progression from November, 1933, to April, 1942. In May, 1942, Kodachrome slides were made as follows: B, pigmentation of the lower palpebral conjunctiva, fornix, and bulbar conjunctiva, shown with the lower lid pulled down; C, pigmentation of the upper and lower lids and the bulbar conjunctiva; D, pigmentation of the upper and lower lids and the upper palpebral conjunctiva, shown with the upper lid everted; E, pigmentation of the upper and lower lids, bulbar conjunctiva, caruncle, and semilunar fold, shown with the lower lid pulled down. At no site is there any elevation of the tumor, except perhaps in the lower fornix. The tumor is in the malignant phase, and exenteration should have been done at a much earlier period. (This case was used as an illustration in a previous article.⁴⁹)

A

Fig. 14 (Reese). A CASE OF CANCEROUS MELANOSIS DEVELOPING FROM PRECANCEROUS MELANOSIS

About 18 years ago, a woman, now aged 45 years, noted a small area of pigmentation on the conjunctiva of the left eye near the inner canthus. Ten years ago the lesion began to increase slowly in size and during the past seven years it has progressed with increasing rapidity.

A. The lesion just before exenteration. There is a diffuse, entirely nonelevated, granular pigmentation of the palpebral and bulbar conjunctiva, caruncle, semilunar fold, and lid margin.

B. A section of the conjunctival tumor. There is an increase in the basal cells which are large, hydropic, and extend into the submucosa and the overlying epithelium. (Hematoxylin and eosin stain.)

come pigmented, swollen, hydropic, and separated from one another by clear spaces. The proliferated basal cells extend into the overlying epithelium and sometimes replace it. They also extend into the underlying stroma.

3. The cells composing a basal-cell epithelioma may show a pigmentation which can be quite marked resulting in a uniformly dark-pigmented lesion sometimes clinically called a malignant melanoma.

4. A papilloma may also be darkly pig-

mented and thereby provoke the diagnosis of melanoma.

The nevus and the malignant melanoma which arises from it have different characteristics from the precancerous melanosis and the subsequent malignant melanosis.

The nevus is congenital, appears as a localized elevated lesion, rarely becomes malignant, but if it does, the resulting lesion is a localized, sometimes slightly pedunculated, single or multiple tumor mass (fig. 8). The tumor in both its benign and malignant phases is completely radio-resistant. Histologically, the malignant tumor is composed of large nucleolated cells with well-demarcated cell borders. The anaplasia may make the cells composing a melanoma arising from a nevus and one arising from a melanosis difficult to differentiate.

The precancerous melanosis is acquired about middle age or later, affects the conjunctiva and/or the adjacent skin in a very diffuse manner with no elevation, gives rise almost inevitably to the most frequent and malignant type of conjunctival and skin melanoma called malignant melanosis characterized by its diffuseness and lack of elevation (figs. 13 and 14-A). In the precancerous stage the melanosis is radio-sensitive, but in the malignant phase it is radio-resistant. Histologically, the tumor arises from the basal layer of the epithelium (fig. 14-B) and has distinguishing histologic characteristics in the benign and in the malignant phase.

Malignant melanosis of the conjunctiva and adjacent skin is by far more frequent than malignant melanoma arising from a nevus. I have seen only one case of a malignant melanoma of the conjunctiva or adjacent skin which could be said with certainty to have arisen from a congenital nevus (fig. 8-B). In five additional cases, however, the melanoma was suspected of having arisen from a nevus, not because of any known preëxisting nevus, but be-

cause of clinical and histologic evidence. I have seen 35 cases of malignant melanosis of the conjunctiva and/or skin of the lids arising spontaneously or from precancerous melanosis.

A review⁴⁹ of the voluminous literature on the subject up until 1942 revealed 42 cases that could be identified as definitely or presumably cases of malignant melanosis. Only two cases could be found which could be identified definitely as cases of melanoma which arose from a preëxisting nevus. One was reported by Lane⁵⁰ and the other by Rosenstein.⁵¹ In the latter case active growth followed a Koch-Weeks bacillus conjunctivitis. Many reports in the literature had to be discarded as unclassifiable because of incomplete data. On the basis of the cases seen by me and the identifiable cases in the literature, the malignant melanosis of the conjunctiva and skin of the lids is 10 to 15 times more frequent than malignant melanoma of nevus origin.

MESODERMAL MELANOBLASTS

These cells are usually long, narrow, and branching, but when their pigment content is increased, they take on a more polygonal or plump shape with few or no processes. Between these two extremes there are transitional stages depending somewhat on the pigment content. These cells are found primarily throughout the uveal tract (fig. 15-inset) and represent the bulk of this tract. They are generally referred to as chromatophores. This term implies that the cell is pigment-harboring rather than pigment-producing. The dopa reaction is negative in the adult but positive for a short period in the embryo. This fact, together with the cell's histologic characteristics in the normal as well as the pathologic state, places it definitely as a true melanoblast. Hereafter this cell will be referred to as the chromatoblast which is more accurate than the term chromatophore.

Fig. 15 (Reese). A MALIGNANT MESODERMAL CHROMATOGENIC MELANOMA OF THE CHOROID. The inset shows the normal chromatoblasts of the choroid. The close resemblance of the tumor cells to the normal uveal chromatoblast can be seen. (Hematoxylin and eosin stain.)

It is generally agreed that the uveal tract is mesodermal in origin. The only other site besides the uveal tract where these mesodermal chromatoblasts occur is subcutaneously as atavistic remains of a pigment system. In higher animals, including the monkey, there is normally and constantly present a subcutaneous pigment system composed of long, branching, mesodermal melanoblasts.

This pigment system of higher animals disappeared in the evolution of man except at one site in the region of the sacrum. This formerly was called the Mongol spot because it was thought to be found only in the Mongolian and Negro

rac^{es}. However, it is known now that this pigment system is found regularly over the sacrum, at least microscopically, in all races in the first year of childhood and disappears after about the fourth year. The spot is first seen in the fourth to fifth embryonal month, even before the pigment in the skin appears. The number of cells and their pigmentation increases at birth and for sometime thereafter. The cells are gradually lost and are seen only exceptionally in adult life. In the Japanese, Jijima⁵² found in all of 25 cadavers evidence of the spot after adult life. The characteristics and behavior of the spot are the same in both the Mongolian and

Caucasian races except in regard to degree. Furthermore, these pigmented cells at their particular site constitute a normal finding during a certain period of life in both the Mongolian and Caucasian races and, therefore, we are dealing solely with the amount or degree of a physiologic occurrence. Clinically, the sacral spot is a localized, bluish pigmentation in an otherwise normal-appearing skin. Microscopically, it is composed of long, branching, pigment cells normally arranged and spaced deep in the cutis with a pigment-free stratum of connective tissue between it and the epithelium. This gives a bluish color to the skin.

Sometimes such blue areas under normal-appearing skin, identical in appearance to the sacral Mongol spot, are seen elsewhere over the body singly or multiply and with or without the spot at the sacrum. Such lesions are called extrasacral Mongol spots.

The sacral spot is viewed as a physiologic variation comparable to the variation in the amount of pigment seen in the iris stroma. The extrasacral spot is viewed as a rest or rudiment of the pigment system normally present in higher mammals but which in human beings has disappeared except in the sacral region.

The blue nevus (Tieche-Jadassohn) consists of a localized compact tumorous mass of mesenchymal melanoblasts simulating in location and appearance the melanoblasts seen in the sacral and extrasacral Mongol spot. The differentiation between an extrasacral spot and a blue nevus may not always be sharp. If the melanoblasts do not form a definite, localized tumor mass but merely an irregular structural arrangement, then there may be some doubt as to the proper designation of the lesion. Practically, however, the difference is merely that in the one we are dealing with a congenital rest of a system only rudimentary in

man; whereas, in the other we are dealing with a benign growth originating from this rest.

The extrasacral spot and the blue nevus are seen principally on the face and extremities and may appear on the lids and bulbar conjunctiva. In an analysis of the microscopic sections of 50 cases of nevus of the conjunctiva, I found that 4 percent were composed of long, branching, pigmented cells which were interpreted as mesodermal chromatoblasts similar to the type found in the uveal tract. From this analysis it seems that the extrasacral Mongol spot and the blue nevus can appear under the conjunctiva as well as under the skin.

Montgomery and Kahler⁵³ have reported on 65 cases of blue nevus occurring in 62 patients. Thirty-eight of the lesions were studied histopathologically. They feel that blue nevi are relatively common and, if looked for, they will be found much more frequently than the literature would indicate. The onset in infancy or in early childhood of a firm, blue to blue-gray papule or nodule remaining as such, without increase in size, usually permits a clinical diagnosis of blue nevus. A malignant change is rare, and, when it occurs, it is a relatively slow-growing melanosarcoma.

Laidlaw² and others have shown that the pigmented cells composing the sacral and extrasacral spots, as well as the blue nevus, are true melanoblasts. They, therefore, represent the only instances of mesodermal melanoblasts outside the uveal tract. Tumors arising from these cells are the only melanotic tumors to which the name "melanosarcoma" can be correctly applied.

Smith⁵⁴ from his tissue-culture studies, found two types of pigment-producing cells in the human being. The one grew like connective tissue and the other like epithelium. The connective-tissue type

Fig. 16 (Reese). AN ANAPLASTIC MALIGNANT MESODERMAL chromatogenic melanoma of the ciliary body. A. Anaplastic cells with the tendency for the densely pigmented cells to lose their processes and become more or less globular. B. Implantation growths to the side of the eye opposite to the mother site of the tumor. Implanted tumor tissue seen in filtration angle (a), along anterior surface of iris (b), in posterior chamber (c), and along the surface of the ciliary body (d). C. A high-power magnification of the implantation growth in the posterior chamber (B-c). These implanted tumor cells show the morphologic characteristics of chromoblasts of the uvea. At (a) is seen a typical branching uveal chromatoblast. (Hematoxylin and eosin stain.)

was found in the choroid, ciliary body, iris, and Mongol spot. The epithelial type was found in the skin, hair follicles, retina, and brain. Of 250 benign pigmented tumors of the skin, he found 96 percent to be epithelial and 4 percent connective tissue. Of 100 malignant pigmented tumors of the skin, he found 67 percent epithelial and 33 percent connective tissue. As pointed out by Stout⁵⁵ his criterion for the malignant group could be criticized on the ground that epithelium can form spindle cells. It is interesting to note that Smith⁵⁴ gives an incidence of 4 percent for the mesodermal melanoblasts which is the same percentage I found from the histologic study of conjunctival nevi.

It is generally accepted that the uvea is mesodermal. The uvea is composed, therefore, almost entirely of melanoblasts which are mesodermal. It is highly improbable that all the melanomas of the uvea are neurogenic or ectodermal, and that no tumor stems from the bulk of the uvea which is the mesodermal chromatoblast. Also, the extremely wide variation in the structure of uveal melanomas indicated by Callender's classification⁵⁶ of spindle cell A and B, fascicular, necrotic, mixed, and epithelioid suggests that in

this group may be included more than one type of melanoma. A similar suggestion is the wide range in mortality, from 6 to 10 percent to 70 to 80 percent, quoted by Callender, Wilder, and Ash⁵⁶ according to argyrophil-fiber content and cytology.

As the result of a study of 410 melanomas of the uvea available in our collection, I feel that, in addition to the neurogenic melanoma already discussed, there is also a chromatogenic melanoma. The cell type of the latter is the mesodermal chromatoblast which gives rise to tumors in the form of benign or malignant chromatogenic melanomas. The cell composing the tumors has, for the most part, the characteristics of the chromatoblast normally identified with the uvea (fig. 15-insert). It is a branching cell which seems to have a tendency to become more globular and lose its processes with an increase in the pigment content (fig. 16-A). In the malignant tumor, there will be found all phases from the typical cell just mentioned to the anaplastic types (fig. 16). These latter cells show a rather large nucleus with a large nucleolus, great variations in the size of the nucleus with a tendency to giant-cell formation, no limiting membrane at the border of the protoplasm, and a tendency for the cells

TABLE 1
CONTRASTS IN THE TWO TYPES OF MELANOMA

	Neurogenic Melanoma	Chromatogenic Melanoma
1. Incidence	++	+
2. Meridian	More often horizontal	No predilection
3. Shape of growth	Flatter	More globular
4. Character of growth	Palisading of nuclei Fascicular and syncytial growth Glandlike arrangement of cells Large cystic spaces Horizontal line in nucleus Nevus cells	Transitional cells from characteristic branching cell to anaplastic cell
5. Pigmentation	+	++
6. Necrosis	+	++
7. Stroma	Large vascular channels	Fine connective tissue septa
8. Disseminated growth	No	Yes
9. Multiple sites	Yes	No
10. Mortality	+	+++

to grow in rows between fine connective tissue septa. The less anaplastic cells may tend to abut on the stroma suggesting the formation assumed by steel fragments towards a magnetic surface.

Table 1 contrasts the two types of uveal melanoma.

COMMENTS ON TABLE 1

1. An analysis of our cases showed that the neurogenic melanoma was twice as frequent as the chromatogenic melanoma.

2. When the neurogenic melanoma involved the choroid, it was twice as frequent in the horizontal meridian as elsewhere. This is thought to be due to the fact that the long ciliary nerves, which seem to be particularly susceptible to benign and malignant pigmented tumors, course in this meridian.

3. There was no great difference in the shape, but generally the neurogenic melanoma was flatter.

4. Rarely the neurogenic melanoma showed a glandlike arrangement of the cells resembling a carcinomatous growth (fig. 4-D). Rarely cystic spaces were present (fig. 5-D). The nuclei sometimes showed a central longitudinal line down the center which was thought to be due to a pyramidal shape of the nucleus.

5. Pigment formation was frequently associated with necrosis.

6. The greater incidence of necrosis in the chromatogenic melanoma is probably a factor in the greater incidence of pigment.

7. The large vascular channels with their accompanying connective tissue constitute the stroma in the neurogenic melanoma.

8. The neurogenic melanoma does not show disseminated growth occasioned by desquamated tumor cells. Such implantation growths away from the primary tumor site are common in the chromatogenic melanoma, especially when the

tumor involves the ciliary body and iris (fig. 16-B, C).

9. The neurogenic melanoma is frequently associated with lesions of the ciliary nerves, such as enlargement of the nerves on the side of the tumor (fig. 5), benign pigmented lesions of the nerve coursing to the site of the tumor (fig. 6), and benign pigmented lesions in the eye away from the site of the malignant lesion.

10. The prognosis of the neurogenic melanoma is much better than that of the chromatogenic melanoma. This is particularly true when the neurogenic melanoma is closer to the peripheral-nerve type (neurinoma or neurilemmoma) than it is to the nerve-terminal type.

Callender has reported on the prognosis of uveal melanoma according to cell type which he divides into spindle A and B, fascicular, necrotic, mixed, and epithelioid. It seems fair to assume that: (1) his spindle cell A and B and fascicular represent mostly neurogenic melanomas which had a mortality of 20+ percent; (2) his necrotic, mixed, and epithelioid were mostly chromatogenic melanomas which had a mortality of 60+ percent.

No effort to date has been made to determine the relative argyrophil-fiber or reticulum content of the two types of melanomas.

CONCLUSION

I have discussed in this presentation tumors which seem to differ genetically, histologically, and clinically but all of which have one factor in common; that is, pigment. However, this one factor is so conspicuous that it tends to dominate the histologic, as well as the clinical picture. I believe that, were it not for this prominent pigment factor, these tumors would be recognized as differing in fundamental respects, including prognosis. Is it not time, therefore, that we cease calling all tumors which harbor pig-

ment "melanomas" and attempt to designate them by various terms which connote their separate entities? The following is suggested terminology:

1. Tumor arising from the Schwann cell and the nevus cell Benign and malignant neuro-genic melanoma.
2. Tumor arising from the pigment epithelium of the retina and ciliary body Benign and malignant neuro-genic melanoepithelioma.
3. Tumor arising from the dilator and sphincter muscles of the iris Leiomyoma.
4. Tumor arising from the pigment epithelium of the iris Dictyoma.
5. Tumor arising from the basal layer of epithelium Precancerous and cancerous melanosis.
6. Tumor arising from the mesodermal chromatoblast (uvea, sacral and extrasacral mon-gol spots) Benign and malignant chro-matogenic melanoma.

THE TREATMENT OF RETINITIS PIGMENTOSA WITH SPECIAL REFERENCE TO THE FILATOV METHOD*

DAN M. GORDON, M.D.

New York

The articles of Filatov and Verbitska¹⁻⁶ and their co-workers, which have appeared in the Russian literature, and which have been partially reprinted in this country in the *American Review of Soviet Medicine*, have again served to focus attention upon the treatment of retinitis pigmentosa.

There has been so much publicity in the lay press, and there have been so many inquiries from physicians and others, that a review of this material, and of other forms of therapy, seems to be in order.

Duke-Elder⁷ prefaces his chapter on the treatment of this condition with the statement, "that the treatment of retinitis pigmentosa is most unsatisfactory, and, indeed, may be said not to exist."

SURVEY OF THERAPEUTIC METHODS

USE OF MEDICAL DILATORS

The association of choroidal sclerosis and attenuation of the retinal arteries has served to focus most of the therapeutic attempts in the direction of obtaining

vasodilatation in the retina. These have consisted of subconjunctival injections⁸ of salt solutions and other substances, inhalations of amyl nitrite and nitroglycerin, paracentesis, the use of miotics, decompression operations, administration of nicotinic acid, retrobulbar atropine injections, and the use of acetylcholine.

USE OF SURGICAL PROCEDURES

It was only natural that the "transient successes" of the medical dilators should be followed by an attempt to obtain more permanent "improvement" by a surgical approach. For a long time, the section of the sympathetics to the eye, by various surgical procedures, was thought to be the answer; and this too has been discarded. Levine⁹ quotes Zehnder as saying, in 1879, that he had noted temporary improvement in cases of retinitis pigmentosa after treatment; but that in no case was this improvement long maintained, and "in no case and through no remedy has there resulted an even transitory improvement in eccentric vision, or enlargement of the contracted visual field."

Dor,⁹ in 1873, and Gunn,⁹ in 1881, both

* Department of Surgery (Ophthalmology), Cornell University College of Medicine.

thought that they saw an improvement in fields and central visual acuity after the use of the constant current. Strawbridge⁹ felt that the current was of no help. Hall,⁹ in 1884, utilized subcutaneous injections of strychnine and administered pilocarpine orally in the treatment of retinitis pigmentosa, and thought that he noted improvement. Redslob,⁹ in 1906, thought that he noted improvements after the subconjunctival use of saline.

Mayou¹⁰ after the trephination of one case of retinitis pigmentosa, which did not have an increased tension, reported, in 1914, "gratifying improvement in the vision and fields." He said that "it is a well-known fact in retinitis pigmentosa that anything which improves the circulation will temporarily improve the vision; for example, amyl nitrite, subcutaneous injections, paracentesis of the anterior chamber. Trephining flushes the vessels with blood. However, these eyes that are operated on, either for the removal of cataract or for trephining, have a great tendency to form fibrous tissue." A year later, Mayou had to report that the improvement in the case just mentioned was transitory, and that in spite of trephination, the disease had progressed.

USE OF GLANDULAR EXTRACTS

In 1918, Jones⁹ thought that he noted improvement after the administration of thyroid-gland extract. Rabinowitz,⁷ in 1931, reported on a series of eight patients, treated with inhalations of amyl nitrite, as suggested by Imre. His period of observation was but 2½ months. Each patient received from 1 to 10 inhalations daily. He reported improved vision (from 0.4 to 0.85) in six patients; enlarged fields in four, with improvements of from 15 to 20 degrees; and improved dark adaptations in four. There were no demonstrable fundus changes.

Wibaut,¹¹ in 1931, introduced the use

of the female hormone. He reported enlargement of the fields and increased light sense. Of five patients treated, one was greatly improved, two moderately improved, one slightly improved, and one unaffected. Wibaut based his use of this form of therapy on the assumption that retinitis pigmentosa was more common in men and milder in women; hence, he felt that the female genital glands exerted a particular resisting power against retinitis pigmentosa. The preparation which he used was Menformon.

Biro¹² stated that he had noted in some patients of both sexes that at puberty a transitory improvement had taken place in their retinitis pigmentosa. He assumed that this resulted from an increased metabolism and a strengthening oxidative energy, due to the fact that the sexual glands have just started to increase in function. Between the years 1932 to 1938, he treated 35 cases with amyl nitrite, sex hormones, and liver extracts. He treated 5 men with testicular extracts; 3 women with glandubolin (a follicular extract); 1 woman with liver injections; 13 patients with amyl nitrite inhalations (7 men and 6 women); and 5 men with a combination of amyl nitrite inhalations and liver injections. He felt that those with dominant heredity are more responsive to treatment.

Of the five men treated with the testicular extracts, four were said to have been improved. Of these four, the vision of one improved from 5/50 to 5/10. This man was said to have retinitis pigmentosa since pigmento. Another patient improved "subjectively." Two others had increases in fields, with return of temporal seeing sectors. In one of these, the field return was quite marked.

Of the three women treated with glandubolin, only one was improved; although another claimed "subjective" improvement. The vision of the one woman

was said to have improved from 5/70 to 5/30. The patient treated with liver extract showed an increase in visual field.

Of the 13 patients treated with amyl-nitrite, 5 were improved. One had a return of vision in the area of the ring scotoma; two had a return of temporal seeing sectors; and one had an improvement of vision from 5/30 and 5/70 to 5/15; another from 5/12 to 5/8; and a third, dramatically, from finger counting to 5/70.

Of the five men receiving both amyl-nitrite inhalations and liver-extract injections, two were said to have improved; vision in one improved from 5/30 to 5/20; in the other from 5/60 to 5/30. These two men had a return of temporal seeing sectors.

Biro felt that field tests are more important than visual tests in evaluating results. Since he did not make any note about changes in dark adaptation, the assumption is that this test was not done. He concluded his treatise with the statement: "But any one of the methods, either the dilating of the arteries or the raising and stimulating of the retina, is capable of improving in some instances, and, even then, to a slight extent. Not so much that it were apt to arouse hope, but at least in such a measure that it would be a mistake to pass over it indefinitely." It is unfortunate that Biro did not give specific data as to the length of follow-ups on his patients.

USE OF AMYLNITRITE AND ATROPINE SULPHATE

Krilloff, Levine, and Tropishko,¹³ in 1934, reported on the treatment of optic atrophy and retinitis pigmentosa by the use of amyl-nitrite, and, later, retrobulbar injections of 1:1,000 atropine sulphate. They noted that the inhalations brought temporary improvement in three of their nine cases of retinitis pigmentosa. When

these same patients were later treated with the atropine injections, they were said to have shown more marked improvements. No conclusions as to the efficacy of the treatment were drawn, although these authors felt that atropine was the better of the two drugs in their hands.

Abadie,⁷ in 1923, introduced the use of retrobulbar atropine injections for the treatment of optic atrophy. Folk¹⁴ used retrobulbar injections of atropine on a large series of patients with optic atrophy and on two patients with retinitis pigmentosa. While he claimed improvements in his optic-atrophy cases, he felt that, in retinitis pigmentosa, atropine has only a temporary effect and has to be repeated. One of his patients with vision of 20/200 and 10/200 showed no improvement. The other, with an initial vision of 3/200 and 8/200, improved to 12/200 and 20/200, only to fall back to his original level within six months.

Brown¹⁵ utilized the same approach in treating six cases of retinitis pigmentosa, half of which were considered to have been improved. Brown's series had an average two-year check. In one case with minimal involvement, the small scotoma in the fields disappeared early in the course of treatment, and had not returned when re-examined two years later. Vision in another case improved from 20/100 and 20/50 to 20/40 each eye. When re-examined two years later, vision was 20/20 and 20/30+2, with larger fields than at the time of the initial examination. A third case, with vision of light perception in each eye, was improved to 20/200. This vision was maintained two years later, but the fields had decreased. A fourth case, with vision of 20/50 and 20/100, improved to 20/40 and 20/100; but after two years had gone to 20/100, O.U. A fifth case with light perception in each eye did not improve. His last case had vision of 20/50 in each eye, with a

heavy ring scotoma. Vision in this case improved to 20/30 and 20/50+1. After four months, vision in the right eye dropped back to 20/50, but after more treatment, improved to 20/30. Two years later, this patient's vision was 20/30-3 and 20/40.

USE OF HORMONES AND VITAMIN D

Giambattista¹⁶ utilized the melanophoric hormone of the pituitary gland, both by topical application and by injection, and claimed improvement in dark adaptation. Arthur A. Knapp¹⁷ noted a retinitis-pigmentosalike change in animals after feeding them a low vitamin-D, low calcium diet. He treated nine patients with retinitis pigmentosa by administering high doses of viosterol and calcium-phosphate tablets; and reported, "definite subjective improvement in all." In five cases, the discs became pinker, and the caliber of the arterioles "seemed to be widened." He had similar results with this treatment in myopia.

VITAMIN-A THERAPY

The well-known association of vitamin A and symptomatic night blindness; plus the known fact that the retina is the richest of all the body tissues in vitamin A; plus the additional fact that the rods, which are the hardest hit of all structures in retinitis pigmentosa, are the richest repositories of vitamin A in the retina, has inevitably led to the use of this vitamin in the therapy of symptomatic night blindness and of retinitis pigmentosa. The success of vitamin A in treating night blindness, not associated with visible disease of the retina, is not the concern of this article.

Levine⁹ stated: "It has yet to be shown that the retina in a case of retinitis pigmentosa is deficient in vitamin A." He used cod-liver oil, by mouth, in large

doses, in the treatment of this condition and was at first enthusiastic about its use. Five years later, he had to admit that the improvements were only temporary.

Givner¹³ has studied a group of 15 patients from the viewpoint of vitamin deficiencies, and has found a lack of vitamin C, only. He has not found any improvement after its administration. He was unable to prove any disturbance in liver functions.

"Satanowsky," in 1934, noted that a deficiency of vitamin A, in retinitis pigmentosa, leads to a disturbance in the regeneration of the visual purple, which may be the cause of secondary atrophy of the rods and cones; because visual purple is necessary for their proper function. Being aware of the role of the liver in the exchange of vitamin A, Satanowsky thinks that the disorders of the liver may be the cause of pigmentary degeneration of the retina."

Parker¹⁹ has recently discussed the role of infectious hepatitis of a chronic nature in the production of night blindness. He found subnormal adaptations in six patients with severe chronic infectious hepatitis, and normal readings in six with mild hepatitis. He gave 3 of the 6 patients with the reduced dark adaptation, 40,000 units (U.S.P.) vitamin A daily, and in one week all showed marked improvement. "Two patients had jaundice during hospitalization, and there was only a slight alteration in their dark-adaptation readings, which were well within the range of error of the tests." Filatov quotes Blegvad as successfully treating hemeralopia and cirrhosis, which appeared with cancer of the liver in a case in 1923, by the parenteral administration of vitamin A.

Josephson²⁰ felt that "one of the fundamental features of the pathologic physiology of the disease is failure of utilization

of carotene and vitamin A." He attempted to treat retinitis pigmentosa by the oral administration of these substances, but noted no improvement. He then gave 30,000 to 60,000 units (new U.S.P.) of carotene in oil, intramuscularly, one to three times per week, and "was gratified to find a rapid and prompt response and relief of the night blindness." He stated that in all the early cases, he noted improvement within a week after starting treatment; "and dark adaptation became comparable to normal, within one to four months, normal in some cases, with a corresponding improvement in the night blindness." He did not note improvement in the more advanced cases with extensive chorioretinal atrophy. He felt that his findings indicated the failure of assimilation of vitamin A and its precursors as an etiologic factor in retinitis pigmentosa.

Litvak² and Verbitska have used Avital, a vitamin-A preparation, intramuscularly, without any results. In March 1938, Tscherkes²¹ (also spelled Cherkes) treated one case of retinitis pigmentosa after the manner of Josephson, and reported marked improvement in dark adaptation. Litvak and Verbitska attempted the use of Avital in another case, in 1938, and noted disappearance of the hemeralopia, and improvement in dark adaptation. Improvement was still present when the adaptation was investigated two months later.

REDUCTION OF INTRAOCULAR PRESSURE

In 1936, at a meeting of the German Ophthalmological Society, Lauber²² reported on the treatment of optic atrophy and of retinitis pigmentosa by the reduction of the intraocular pressure. He discussed the relation between blood pressure, intraocular pressure, and intracranial pressure. He felt that if the blood pressure was lowered or low, in patients

with tabes, optic atrophy tended to develop during these periods of lowered pressure; and that with a return of the pressure to normal, the atrophic process comes to a standstill. He also felt that the disastrous effects of certain antisyphilitic drugs was due to the fact that these lowered the blood pressure. He reasoned then, that two sources of treatment were available: either to raise the systemic blood pressure or to lower the intraocular pressure. He stated that it had been possible to bring the pathologic process to a standstill, in many cases, by medically or surgically lowering the intraocular pressure. At the same time the general condition of the patient was improved by the use of strychnine and various glandular preparations. Failure was due to inability to achieve this aim.

The same treatment was applied to 21 eyes with retinitis pigmentosa, most of them far advanced; in 14 eyes, vision "improved," and in more than "half of these, the visual fields too became larger." In some eyes, the improvement lasted more than six months. In five eyes, the condition has remained unchanged, after improvement for a time in one eye; in two eyes, a temporary improvement was followed by a worsening, with recurrence of the ocular hypertension. He stated that retrobulbar injections of atropine should be deleterious, due to the creation of a hypertension.

Sobanski²³ used a similar approach to the problem, employing cyclodialysis plus strychnine. He treated nine cases with seven improvements, three of which were temporary.

Levy-Wolff²⁴ quotes Nizetic, Spiridonovic, and Bukorov as having treated three cases by sympathectomy, plus pilocarpine or cyclodialysis for pressure. They obtained improvement only if they used the tension-reducing measures.

PERMANENT DILATATION OF RETINAL VESSELS

It was inevitable that a more central approach to the problem should be instituted. In 1930, Royle²⁵ reintroduced the concept of producing a permanent dilatation of the retinal vessels by employing a section of the sympathetic nerve supply to the eyes (Duke-Elder credits Abadie with having first suggested the idea in 1901). Royle's suggestion was greeted with considerable enthusiasm; and the method, if one is to judge from the literature, was attempted universally.

Various surgical approaches and techniques were employed, in an attempt to obtain a more perfect result. Royle practiced division of the branches of the first thoracic ganglion and removal of the ganglion. Caeiro, Malbran, and Balza²⁶ also employed a similar procedure which they refer to as "stellotomy." Meighan²⁷ performed a resection of the superior cervical ganglion, plus periarterial sympathectomy of the carotid artery. McKenzie²⁸ performed a similar procedure, plus a resection of the middle cervical ganglion. According to Whitnall,³⁰ superior cervical ganglionectomy should suffice to insure a complete denervation of the sympathetics here.

The underlying rationale behind any form of sympathectomy was the hope that an exaggerated vasomotor tonus was responsible for the attenuation of the retinal arteries. The permanency of the vasodilation, after sympathectomy, is still a matter of dispute. While the immediate effect of the sympathectomy is vasodilation, vascular tonus is regained within a few weeks.

In his first paper, Royle reported on six cases treated with sympathectomy. Vision in the first patient was not even hand movements at four feet. Two weeks postoperatively, this man could tell time on a clock and, finally, six weeks postopera-

tively, he was able to read typewritten letters. Vision in the second case was 6/60; and fixation was too poor to enable a field to be taken. One- and one-half months postoperatively, the patient's vision was 6/60 and 6/36. The report on four other patients was "too early to state the results accurately," but some improvement in vision and fields was shown.

In 1932, Royle reported on 15 cases. Dr. E. A. Brearley was quoted by him as noting that the ipsilateral retinal vessels were almost invariably dilated postoperatively, and that this was permanent. Nine of Royle's cases had had loss of central fixation for years; and in none of these was permanent improvement noted.

In the other five cases seen by Dr. Brearley, four patients had maintained their improvement, and one had lost ground after an immediate response. The results in these five cases, plus a sixth, seen by another ophthalmologist, were:

Case 1. Vision was 6/60 in each eye. Fields were unchartable. Five months postoperatively, vision was 6/60 and 6/24, and fields were within 10- to 20-degree circles.

Case 2. Vision was 6/6 in each eye. There were 20- to 30-degree fields postoperatively (17 months), vision was unchanged. Fields had enlarged to almost normal.

Case 3. Vision was 6/60 and 6/18. The right field was less than, and the left slightly more than, 10 degrees. Three months postoperatively, vision had increased to 6/36 and 6/12, and then returned to original preoperative vision. The left field was slightly enlarged.

Case 4. Vision was 6/60 in each eye. Fields could not be charted. Two months postoperatively, vision was 6/24— and 6/60. Field for the right eye was 10 degrees.

Case 5. Vision was 6/60 in each eye. Fields were to the fixation point. Three

weeks postoperatively, vision was 6/36 and 6/60. The right field had increased to between 10 to 20 degrees.

Case 6. Vision was 6/24 in each eye. There were 10-degree fields. Ten months postoperatively, vision was 6/9 in each eye. Fields had increased to 18 degrees. (Case of Dr. C. Thomson.)

Royle cited the recovery of hearing in one mute; and an improvement of hearing in one case of deafness. Royle's fields are open to question, in that they show concentric enlargement as a sign of improvement. It has been my experience, as well as that of a large number of the authors quoted here, that where improvement in the field occurs, it frequently is in the direction of return of peripheral (usually temporal) seeing areas. Royle's series includes no such case, even though he has cited large improvements in some of his cases.

MacDonald and McKenzie,²⁸ in 1934, reported on four cases treated by sympathetomy, with the following findings and results.

Case 1. Vision was 5/60 and 6/60+1. Fields were down to fixation. Twenty-six months postoperatively, vision was 6/60 and 5/60. Fields remained unchanged.

Case 2. Vision was 6/60 and 6/36. Fields were between 20 to 30 degrees. Twenty-four months later, vision was 6/36 and 3/60. Fields have decreased to the 5-degree circle.

Case 3. Vision was 6/24 and 6/12. There were 5-degree fields. Twenty-four months postoperatively, vision was 6/24 and 6/12, and there was a slight increase in fields.

Case 4. Vision was 6/12 and 6/24. Fields were 15 to 20 degrees. Six months postoperatively, vision was 6/12 each eye, and the right field had definitely increased.

In this series, one eye definitely shows

an increase in vision and field; and, conversely, one eye (case 2) shows a marked decrease in vision, postoperatively.

Campbell²⁹ reported one case with vision of 6/12 in each eye, and with 3-degree fields. After sympathetomy, vision remained unchanged, although there was a return of a superior seeing island in the field. This disappeared after six months.

Walsh and Sloan³⁰ reported three cases, in 1935, which were treated by sympathetomy. The findings in their series were:

Case 1. Vision was 20/40 in each eye. Five-degree fields were present. There was no improvement postoperatively.

Case 2. Vision was 20/50 and 20/40. Fields were 17 to 20 and 12 degrees. One month postoperatively, vision was 20/70 and 20/50. Fields were unchanged.

Case 3. Vision was 20/200 and 20/30-3. Right vision was corrected to 20/100. The patient was unable to read Jaeger type with the right eye. Left vision was J1 at 6 inches. This patient was carefully followed for a period of 14 months, and no improvement in vision was noted, despite her assertions of visual improvement. There was definite improvement in fields and in dark adaptation, but eventually there was a return to preoperative levels.

Meighan,²⁷ who, at the 1931 congress of the Ophthalmological Society of the United Kingdom, had reported on one case improved by sympathetomy, again reported on the same subject, in 1935. At that time, he stated that the original case had now regressed to the point where the patient was worse than before treatment. Two other cases had been similarly treated; one showed slight improvement in vision; but both showed progressive contraction of the fields. Meighan felt that this progressive contraction of the

fields indicated that the disease had not been arrested.

Gifford and de Takats,³¹ in 1935, reported on six similarly treated cases.

Case 1. Vision, corrected, was 6/12 in each eye. There were 20-degree fields. Postoperatively, vision was 6/10-1, with no change in fields.

Case 2. Vision was 8/10 in each eye. Fields were within 10-degree circle. There was no change, postoperatively.

Case 3. Vision was 18/200 and 20/200. Fields showed loss of the upper half and a central scotoma on each side. Operation did not improve the condition.

Case 4. This case had previously received 10 subcutaneous injections of uveal pigment, with no change in her findings. Vision was 20/40 and 20/20-3. Postoperatively (5 to 8 months) vision was 20/40+2 and 20/15-2. Visual fields had contracted.

Case 5. Vision was 20/20 and 20/40+1. Fields were 10 to 20 degrees. Postoperatively, vision was 20/40-1 in each eye, with a decrease in the right field.

Case 6. Vision was finger counting and 20/50. There was no change after surgery.

These authors felt that their results definitely failed to confirm the enthusiastic reports in the literature. They sounded a note of caution and pointed out that one of Magitot's patients had remained dizzy and had suffered occipital headaches for months, postoperatively.

In 1933, Caeiro, Malbran, and Balza²⁶ presented five patients treated by stellectomy. Their results follow.

Case 1. Vision was light perception and 1/8. Fields were 5 degrees. Vision showed a postoperative improvement to 20/20 (L.E.) 11 days later. The left field was increased to 15 degrees, temporally.

Case 2. Vision was 1/8, O.U. Fields showed 5 degrees. Three months postoperatively, vision was 1/3 and 1/4; fields had increased to 10 degrees.

Case 3. Vision was improved in two months from perception of large objects to 1/20. Fields were not done.

Case 4. Vision was 1/6 in each eye. It was improved in one week to 1/3 and 1/4. There was no improvement in fields.

Case 5. Vision was: R.E., large objects; L.E., 1/8. Fields were 5 and 10 degrees, respectively. One week postoperatively, vision was 1/50 and 2/3. The left field had increased to 20 degrees.

Two of these patients (cases 3 and 4) had been previously treated for syphilis.

In 1938, Caeiro³² again reported on the results of stellectomy. He quoted Campbell's and Meighan's good results; a claim not made by these authors, nor upheld by a review of their reports. He, at this time, also referred to three cases operated by Drs. Villegas and Pasman, who obtained "flattering" results. He did advise caution in the interpretation of results. He definitely felt, however, that "patients who have been operated on by this method have shown real improvement, and these results, whether based on quackery or on scientific principle, are eloquent."

It is probable that Caeiro did not intend the word "quackery" to be used in the American sense; but rather to denote lack of scientific rationale. Caeiro did not believe that the effect of ganglionectomy on the capillaries wears off after a short time; but quoted Diez to the effect that "experience has proved that with this operation the phenomena of vascular expansion that are obtained are persistent, or, at least, last a long time."

Caeiro divided his cases into two series. One series of 13 patients (including the four recorded above) were operated on without consideration of the degree of progress of the ailment. In addition to the four reported whose "increase in visual field and visual keenness" still persisted five years later, four had a slight improvement and four no change. The

last obtained much improvement in vision and field, "lost within six months almost all that he had gained; a slight improvement in visual keenness nevertheless persisted."

The second series included more carefully selected cases, all operated upon two years prior to publication of the article in 1938. The results in the second series follow.

Case 1. Vision was $1/3$ and $1/4$. Fields were 20 and 25 degrees. A month after operation vision in the left eye (operated) was $1/2$, and that field had been extended to 40 degrees. Data on the right eye were not given. It was stated that examination three months later still showed improvement.

Case 2. Vision was $1/5$ and $1/4$; fields were 50 to 70 degrees, and 0 to 60 degrees. Five months postoperatively, vision was $1/3$ and $1/2$. One field remained unchanged; the other went from an original of 0 degrees temporally to an increase of 50 degrees. Three months later when the patient was examined "he was found to be doing well."

Case 3. Vision was 0 and $1/10$. The field on the eye with vision showed 55 to 80 degrees, with a large central scotoma, covering 25 to 55 degrees of the central field. Examination almost three months after surgery revealed vision to be: ability to distinguish bulky objects and $1/6$. There was some increase in field.

Case 4. Vision was counting fingers at 3 meters and $3/10$. Fields were 25 to 50 degrees, L.E.; and contracted temporally to 50 degrees, R.E. Four months postoperatively vision was: the $3/10$ eye had increased to $1/2$; vision in the other eye was not given. Fields were essentially unchanged.

Cacero concluded with the statement that four other patients had been similarly treated, with good results, but were not being reported because the period since operation had been too short.

It is worth noting that Cacero has obtained unusually large fields on patients with poor vision. At the same time, it should be pointed out that he did not elicit any ring scotomas in his preoperative examinations. Nor did he elicit any such scotomas on examination of any of his improved cases.

Kerr,³³ in 1935, reported on the series of cases which he had operated for Dr. Louis Greene. They saw 18 patients with retinitis pigmentosa, five of whom were blind. Of the remaining 13 patients, only eight showed fields. Of these eight, three patients who had good fields obtained excellent results; and the five with gun-barrel fields obtained no results.

Greene and Kerr's first case showed a 50-percent improvement in visual acuity; and 150-percent increase in field. Their second case had vision of $20/40$ and $20/70$, which was improved to $20/20$ and $20/30$, while the fields were improved to almost normal. Their third case went from $20/100$ to $20/20$ in each eye, with almost normal-field returns. Their fields, also, showed concentric enlargement without the ensuing return of a ring scotoma during the period of enlargement. They had one postoperative death, occurring the next day.

Grant,³⁴ at a meeting of the College of Physicians of Philadelphia, in 1940, reported on the late results of cervical sympathectomy in retinitis pigmentosa. He used the high operation of carotid stripping of the internals, common and externals, with excision of the upper and middle cervical sympathetic ganglia, and the intervening nerve. Reporting on nine cases, he stated that he thought that they became worse more slowly than did similar control cases which were not operated. Spaeth, in discussing this paper, tended to agree with Grant's findings; and commented upon the tremendous variability in the fields, postoperatively. He commented

upon the number of new retinal vessels seen postoperatively.

Zaven and Govaerts,³⁵ in 1940, reported one case similarly treated, with no improvement. Blobner,³⁶ following the reports of Magitot, which were enthusiastically in favor of sympathectomy, attempted this procedure on six cases. He obtained no improvement and felt that the operation should be done away with, since it did no good and could do harm.

Karsch,³⁷ in 1936, attempted a critical review of all the therapeutic procedures which had been attempted in retinitis pigmentosa, from 1887 to 1935, and concluded that nothing substantial had been added to our therapeutic armamentarium. He suggested that the work of the Japanese, Sgrosso and Sukanura, with roentgen therapy, be followed, as he felt that this might offer some hope.

Crisp,³⁸ in 1937, in an editorial on the subject of therapy of retinitis pigmentosa, quoted Doyne as having administered raw ox retina and sheep retina, without results. Clegg had tried a glycerine emulsion of sheep retina with similar negative results; while Seggel had combined injections of strychnine with the administration of cod-liver oil and liver.

In 1940, Mutch and Macky³⁹ commented on Dax's work with melanophore-dispersing hormones, and offered the suggestion that the B hormone, or melanophore-dispersing hormone, might offer some future hope. They were, however, unable to prove their point in several attempts on patients. Their results differed from those of Giambattista, referred to earlier in this paper.

The multiplicity of the therapeutic agents employed in retinitis pigmentosa, and their uniform failure to obtain or maintain a lasting improvement, plus the general failure of other observers to repeat successes claimed by the originators of these modes of therapy, indicate that,

today, retinitis pigmentosa must still be classed as a hopeless disease.

THE FILATOV^{1a} METHOD

Filatov and Verbitska have introduced the concept of "tissue therapy" for the treatment of retinitis pigmentosa and other ocular diseases, as well as for some nonocular conditions. They employ the intramuscular injection of cod-liver oil, as well as implantations of liver, skin, placenta, and other tissues under the skin. They have also utilized subconjunctival implantations of placenta, with or without a scleral trephination. They have treated over 110 patients by this method. It is the purpose of this paper to outline their methods of treatment, along with some comments as to their results; especially in view of our own experience with this method.

Filatov's theory is that, when tissue has been removed from the body under aseptic conditions and allowed to stand 6 to 7 days at $+2^{\circ}\text{C}$., certain disintegration substances are released.

These disintegration substances act as vital stimulants when the tissue is implanted or its extracts are injected. This action is not a specific one for any particular organ. He believes that it is this stimulation, and not the vitamin content alone, which produces beneficial results. Since each gram of U.S.P. cod-liver oil contains "not less than 850 U.S.P. units of vitamin A, and not less than 85 units of vitamin D," it would appear that for each cc. of the oil injected the vitamin content would not be very great. It would also appear that some other substance or substances in the material might well be credited with the results which Filatov claims.

METHODS OF PRÉPARATION

Filatov prepared his cod-liver oil by sterilization in a boiling water bath for 15 minutes, for three consecutive days. This oil was later poured into ampules,

and heated to 60 to 70°C., two hours daily, for three days. According to Filatov and Verbitska, sterilization did not destroy the vitamins and the liver products, and bacteriologic examinations were negative. They started with 0.5 cc. doses intramuscularly, and later increased the doses to 1 cc. and then to 2 cc., given three times weekly, with the series consisting of from 10 to 24 injections. Each injection was followed by two to three minutes of local massage.

Sterilization of the oil in ampules, with the addition of nitrogen to prevent oxidation, is the safest and best method of preparation. This is the method which we now employ, using a 1-percent-procaine base to prevent or minimize the delayed reactions, which have accompanied the use of cod-liver oil injections. With this preparation, larger doses are now being used.

Filatov has also used by implantation or injection many tissues, which he feels contain these "biogenic stimulators." He has found these "stimulators" in the skin, liver, spleen, subcutaneous tissues, muscle, cartilage, and in various eye tissues, as well as in the placenta. He has also found them in various plants; for instance, in the leaves of aloe and pea sprouts, which he conserves in the dark.

The material is removed from the bodies of persons, who have died from noninfectious diseases or from trauma, within 10 hours of death. It is removed under strictly aseptic conditions and stored in a dry-sterile bottle for seven days, at a temperature of 2 to 4°C. He states that all spirochetes have disappeared by this time, and quotes his colleagues, Walter and Glaiberman, as having shown by serologic and other tests in several thousand cases that no syphilis is present. He implants small pieces of tissue, principally liver or placenta, subcutaneously, usually in the subcostal region. These subcuta-

neous pockets are about 3 to 4 cm. in width, and the small fragments which he implants into them are equal to about 6 cc.

We have attempted one liver implant, without untoward effects. Of the first four specimens of human liver which we obtained at autopsy, three were rejected after having been cultured in deep broth for one week. Sterile liver can be obtained in the operating room.

"Subconjunctival implantations of placenta, and other tissues, is performed as follows. The material is refrigerated for seven days. After subconjunctival injection of 2 cc. of 0.5-percent solution of novocaine, to produce edema, a small incision is made in the conjunctiva, which is undermined at least 2 cm. A segment of placenta, 12 to 15 cu. mm., is introduced deep into the channel. With his forceps, the surgeon then grasps the placenta together with its overlying conjunctiva, and holds the two tightly for a few seconds to keep the implant in place. No sutures are required. This operation can be done in the out-patient department." Filatov has similarly implanted choroid and retina, cornea, and tarsal material.

Intramuscular injections of placenta and other tissues, are prepared by Filatov as follows. "Ten parts of distilled water are added to the finely macerated tissue and the mixture is kept for one hour at room temperature, and for another hour at 70°C.; it is then filtered several times. When the protein content does not exceed 6 mg. percent, the liquid is transferred to ampules which are kept at room temperature for three days, except for one hour daily during which they are tyndallized at a temperature not above 70°C. After testing for bacteria, the ampules are placed on ice."

APPLICATION AND RESULTS OF THERAPY

Filatov and his co-workers have used

this therapy in practically every eye disease and have claimed improvements and cures in many of these. Some of the conditions for which they have made such claims are: keratitis, conjunctivitis, blepharitis, corneal tuberculosis, herpetic keratitis, hypopyon keratitis, corneal ulcers and opacities, keratoconus, uveitis, myopic chorioretinitis, optic atrophy, glaucoma, and trachomatous pannus. It has also been used to increase function in healthy eyes when various somatic disturbances are present. A complete table of the results of Filatov and Verbitska's

TABLE 1

RESULTS OF SOME CASES OF RETINITIS PIGMENTOSA
TREATED BY FILATOV AND VERBITSKA

Method of Therapy	No. of Cases	No. of Successful Results
Injections of cod-liver oil..	60	52
Subconjunctival implants of placenta.....	22	22
Subdermal implants of placenta.....	6	—
Subdermal implants of preserved skin.....	5	—
Transplantation of skin...	17	7
Total.....	110	81

treatment of cases of retinitis pigmentosa is not available, but some of their results are shown in Table 1.

Filatov and his co-workers have recorded improvements in visual acuity, fields, and in dark adaptation. Their follow-ups, as recorded, have been brief, for the most part. However, he does note one improvement lasting seven months, and another lasting 2½ years. He has charted increases in both central and peripheral fields and increases in light sensitivity of from 5 to 1,000 times.

Filatov has also used combinations of the injections (usually of cod-liver oil) and the subdermal or subconjunctival implantations. He does not discuss in detail

the average duration of the "improvements;" nor does he discuss the question of a "maintenance dose." He does state that in cases in which the improvement has been lost he has been able to bring it back with another series of treatments.

DISCUSSION

A survey of the literature on the therapy of retinitis pigmentosa leaves the reader very confused. In spite of the vast array of therapeutic agents which have been presented in over half a century, the disease is still a hopeless one. The marked variation in results which different reliable observers have obtained with the same modes of therapy is difficult to explain.

As one reads the detailed descriptions of the various cases treated and of the results claimed, it becomes obvious that there is not a complete agreement on just what constitutes retinitis pigmentosa; on just what amount of "improvement" is an improvement; or on just what amount is a normal variation.*

Filatov's work on "tissue therapy" has been greeted with considerable skepticism in this country. This skepticism has been heightened by the fact that his reports have not been up to the American standards of scientific reporting either in detail or in the length of follow-ups.

I must admit that, when the subject was brought to my attention, my first reaction was one of skepticism. However, in spite of the fact that they are panacealike in nature, the claims of a man of Filatov's reputation merit study before being discounted. With that purpose in mind, a study of his methods has been embarked upon, and up to January 1, 1947, 109 patients suffering from typical or "atypical" retinitis pigmentosa have been, or are being, treated.

* The author intends to discuss this subject in a later article.

EXPERIENCE WITH FILATOV METHOD

It is not the intent of this article to serve as a preliminary report of the work which we are doing at the New York Hospital. However, some comments concerning our experience might be of value to others desiring to attempt this work. Our therapy was begun in June, 1946, and thus far (January 1, 1947) has been concerned mostly with the cod-liver oil injections or their modifications. Some of Filatov's other methods are also to be attempted.

Originally, a small series of patients was selected, with the idea of conducting a pilot experiment to determine whether the method warranted more intensive study. Since facilities for dark-adaptation tests were not available at that time, only one patient in this series had these tests. No study of this type would be complete without dark-adaptation determinations, which are now being done. Our studies included complete ophthalmoscopic and slitlamp studies of the eyes, with visual fields, visual acuity, and tensions. Special attempts were made to elicit ring scotomas and peripheral seeing areas.

As a result of the "improvement," noted in some of the original series, a more complete study on 109 patients is now being carried on. These improvements were in the direction of increase in visual acuity, of increase in field, and of gross improvement in ability to get about in poorly illuminated rooms, and so forth.

Many of these patients stated that they noted less need for dark glasses in the sunlight and that they had less discomfort in the sun. Others commented on the fact that "things are less hazy" and that their eyes were less tired. Incidentally, a common complaint of these patients is that of "tired eyes." Whether this is due to their habit of squinting or to the rapid exhaustion of the few patches of functioning retina which they have, or to both, is not

clear. This has not been stressed before as a common symptom.

One man who had to change his occupation because of his failing vision and who had formerly been an excellent badminton player, reported that he was again able to play a "good game of badminton." He also noted that he no longer needed his sun glasses when he was driving and gardening.

Another man who had had one eye enucleated stated that he had been unable to play ping pong for 12 years, because he had "missed 15 out of every 16 shots." He returned from his vacation, taken immediately after a course of 15 injections of the cod-liver oil, and stated that he was again able to play, and to "hit 15 out of 16 shots." Although some of the "improvements" were definitely psychologic in nature, one was impressed by the apparent reality of others.

In addition to an initial improvement in visual acuity, there is a tendency for the peripheral seeing area to return, or for the present one to enlarge. In our experience, this improvement has been almost always in the far temporal periphery. At this time, it is not possible to discuss fully the changes in dark adaptation, but it is our impression that dark adaptation improves in some cases. Changes of illumination cause these patients considerable suffering, and these treatments have given relief in some instances. Tolerance to light also improved in some cases. Most of the patients complain of "hazy" vision, and some have stated that this tends to clear.

TECHNIQUE USED

At present, a series of injections consists of initial doses of $\frac{1}{2}$ cc. to test sensitivity; followed by four injections of 1 cc., and 15 injections of 2 cc. or more. Injections are given three times weekly. Obviously, June, 1946, to January, 1947,

is too brief a time to permit extensive follow-up studies. However, the improvements in the cases treated have for the most part been of fairly short duration, lasting four to six weeks or a little longer. It is quite possible that we shall find the durations of improvement to be as variable as did Filatov.

The injection of cod-liver oil is not a simple mode of therapy. We have noted a number of local and some systemic reactions. The injection is not immediately painful and does not require the concomitant use of any local anesthetic. About 48 to 72 hours after the injection, a local reaction occurs; and, in some cases, fever and a chilly sensation. The effect seems to be cumulative. Areas which had been injected a week or more before may now start to become inflamed. On several occasions, it seemed that large abscesses were forming, but in each case, the reactions responded to local applications of heat or ice. Some patients have been incapacitated for as long as one week. We are under the impression that, the more the material is sterilized, the more severe the local reactions. Men seem to be able to tolerate the injections better than do women. The local reactions, at the site of injection, have varied from slight to severe. We have used the biceps region as well as the gluteal, with reactions being no greater in the former site than in the latter.

As this work continues, an attempt will be made to determine the irritating factor. Various preparations will be tried; namely, cod-liver oil without vitamins A and D; carotene and the various isomers of vitamins A, A and D, A and E; various other fish oils and their fractions, either together or in succession; and cod-liver oil concentrates.

Filatov states that he does not know the chemical nature of the substance responsible for the "biogenic stimulation." One

can only conjecture at this time; but it is important to note that the sterols are found in large quantities in most, if not all, of the substances which he mentions as sources of supply.

DISCUSSION OF EXPERIENCE

The first problem that confronts the investigator in this field is to determine the merits of this form of therapy. Assuming that there may be some merit in it, the next problem is one of determining the average duration of the improvement and the possibility of working out an adequate maintenance dose.

Further work, after adequately testing Filatov's methods, would then be in the direction of improving upon this means of therapy. In its present form, it is not the final answer to the treatment of retinitis pigmentosa.

An honest evaluation of any mode of therapy, which seems to offer hope of improvement in an appreciable percentage of cases, cannot be hurriedly made, unless 100 percent of a large series of cases show no improvement. When a certain number of cases do show evidence of improvement, it is important to determine whether that improvement is actual, or whether it is only within the limits of normal variation.

If improvement seems to be actual, then the true test of the value of that therapy is its ability either to maintain that improvement for an appreciable period of time, or to restore it, in case of regression, by additional administration of the therapeutic agent. Since the injections of cod-liver oil have resulted in some improvements, any preliminary report would be premature until the other qualifications—is improvement actual, can it be maintained or restored—have been more fully studied.

Until such time as its merit has been more fully determined, it would be sing-

ularly unfortunate if large numbers of ophthalmologists rush into action with this therapy and attempt to evaluate it on very small numbers of patients.

Filatov has not claimed any cure for retinitis pigmentosa. His claims for improvement run as high as 100 percent in one series (Table 1) and are certainly impressive, if they can be substantiated. In analyzing some of his case reports, it would appear that some of his "improvements" tend to fall more properly under the category of normal variations. Other results, however, are of such magnitude as to be considered as improvements.

CONCLUSION

A review of the various therapeutic attempts in retinitis pigmentosa has been presented, with especial attention to the details and claimed results of the Filatov method of tissue therapy. No attempt has been made to include a preliminary report of the work with this method, now being carried on at the New York Hospital. However, an attempt has been made to guide the investigator in this method, on the basis of observations made during the work at this Hospital.

PERIPHERAL VISUAL ACUITY*

WITH SPECIAL REFERENCE TO SCOTOPIC ILLUMINATION

JOSEPH MANDELBAUM,[†] M.D.

Brooklyn, New York

AND

LOUISE L. SLOAN,[‡] PH.D.

Baltimore, Maryland

The capacity of the retina to discriminate form decreases rapidly just outside the fovea and continues to diminish peripherally. Wertheim's classical data¹ show a steep drop in relative visual acuity from 1.00 at the fovea to 0.46 at 5 degrees, and then a slower drop to 0.20 at 10 degrees. An acuity of 0.20 could still be measured at 20 degrees. Ludvigh's measurements² roughly parallel these, the decline being even more precipitous in the paracentral region. Only 0.26 of the central acuity remained at 5 degrees, and 0.15 at 15 degrees. His data showed a relationship between peripheral visual acuity and the population of cone cells in the retina as given by Østerberg.³ The near parafoveal region was studied intensively by Weymouth and others,⁴ who showed that acuity falls off immediately and continuously from the foveal fixation point.

All these investigations were performed at high levels of illumination in order to demonstrate maximum acuity (Ludvigh used 26 to 36 foot-candles; Weymouth 18 millilamberts). No study of peripheral acuity under scotopic levels of illumination could be found. However, scotopic acuity measurements are of particular importance, because it is precisely under scotopic illumination that the peripheral

retina is called upon to take over the discriminatory functions. Only in the pathologic eye with a central scotoma is eccentric photopic acuity of prime importance; eccentric scotopic acuity is of importance in all eyes. It is quite plausible that with high illumination, peripheral acuity should parallel the cone population, as was pointed out by Ludvigh. Would scotopic measurements indicate a similar parallelism with the rod population? The rod population has its maximum density close to 20 degrees peripherally;³ the sensitivity of the retina to light is also greatest in this region.⁵ However, there were several reasons to believe that peripheral scotopic acuity need not follow this pattern. In the first place, if night-blind subjects are excluded, there is little correlation between light sensitivity and scotopic form discrimination.⁶ Furthermore, it has been the experience of many subjects familiar with various methods of testing scotopic form discrimination, such as were employed by the Army Air Forces, that fixation at an angle much smaller than 20 degrees gives maximum acuity in these tests. Finally, there is the theoretic reason that the maximum in light sensitivity attained at about 20 degrees is caused in part by a maximum summation of impulses from the individual rod cells, many cells in this region being connected synaptically with a single nerve fiber. This anatomic adaptation, providing maximum light sensitivity, does so at the expense of form discrimination, since the participating units in the retinal mosaic are very much larger.

* The measurements reported in this communication were performed at the Army Air Forces School of Aviation Medicine, Randolph Field, Texas.

METHOD

A Clason Acuity Meter was used to project the visual acuity pattern on the center of a white screen in a darkened room. The form used was the Landoldt ring. Slides were constructed, each providing presentations of the ring with the break in the up, down, right, and left positions. Three slides were used, with rings 2, 6, and 12 mm. in diameter. With these slides and the continuously variable magnification the instrument provided, the diameter of the projected image could be varied from 12.5 to 245 mm.

The intensity of the projected light beam (the acuity pattern was black on white) was varied by means of neutral filters in steps of 1 log unit (10-percent transmission) and an iris diaphragm calibrated in steps of 0.3 log unit (50-percent transmission). The highest light intensity used was 9.0 log micromicrolamberts (approximately 1 millilambert). This intensity, although not sufficiently high to give maximum photopic acuity, is nevertheless well up in the photopic range, and sufficiently high to offer a basis for comparison with the lower scotopic levels in which we were primarily interested. The lowest intensity at which measurements were made was 4.3 log micromicrolamberts (0.00002 millilamberts).

The direction of fixation was controlled by means of a movable red fixation light. A 7-watt incandescent lamp, enclosed in a small housing, illuminated a 1-cm. circular aperture which was covered with a red filter and a neutral filter of density 2.0. The light in its housing was suspended behind the screen so as to illuminate one of a series of 3-mm. circular holes in the screen. The holes, with the exception of the one in use as a fixation point, were covered with white cardboard discs so as not to interfere with the projected pattern. When the desired fixation distances were greater than 35 cm.

(the screen was 70-cm. wide, and fixation distances were computed from its center); the fixation light was merely suspended at the desired distance off the screen.

Most of the measurements were made in the horizontal meridian. In order to facilitate the maintenance of correct peripheral fixation, the Landoldt ring was flashed on the screen for exposures of $\frac{1}{5}$ second. The short exposure, achieved by the introduction of a photographic shutter in the illumination system, insured that the subject did not move his fixation while he was making an observation. The success of this method was attested to by the fact that the after image of the projected light always bore the correct relationship to the fixation light.

Measurements of acuity were made at the fovea and peripherally as far as 30 degrees. It was found that accurate foveal measurements could not be made with the brief $\frac{1}{5}$ -second exposure, for it was never possible to be certain that an actual foveal measurement had been made. In the paracentral regions it is unimportant if a small error is made in the exact fixation angle recorded. However, even the slightest error is of significance in a supposedly central measurement. For the central measurements, therefore, the exposure of the test object was not limited; hence, the data for central measurements are not directly comparable with the paracentral measurements. An attempt was made to estimate the error introduced by not limiting the central measurements to $\frac{1}{5}$ second. It was found that at the highest brightness central acuity increased from 0.75 to 1.13 when the exposure time was increased from $\frac{1}{5}$ second to several seconds. In the paracentral areas, the difference was less marked. In peripheral areas, such as 20 degrees from the fovea, no increase at all was obtained; on the contrary, longer exposures caused the image to blur and disappear.

An experimental run consisted of visual-acuity measurements at a single retinal location for the entire range of illuminations. The highest intensity was employed first ($9.0 \log \mu\text{l}$), and then successively lower intensities down to the lowest ($4.3 \log \mu\text{l}$). Each run required approximately 45 minutes. During this time the eye of the observer became adapted to the progressively lower intensities to which it was exposed. The minimum visual angle at which 75 percent of the presentations were properly identified determined the visual acuity. Observations were made chiefly at a distance of 4 meters from the screen. For the higher intensity levels, for readings at or near the fovea, it was necessary to increase this distance to 8 or 10 meters in order to provide sufficiently small visual angles. In order to measure acuities lower than 0.022, the distance was diminished to 2 meters.

RESULTS

The right eye of one trained observer was studied intensively, and several measurements were made on the eyes of 18 other observers. Because of the great range in light sensitivity found in a normal group (1 log unit, a factor of 10), acuity measurements for different observers might not be comparable, and it was necessary to consider the entire range of data for all intensity levels and retinal locations of each subject as a unit.

The visual acuity for subject L. L. S., measured in the horizontal meridian from the fovea to 30 degrees peripherally at 17 brightness levels, is given in Table 1. More measurements were made for the temporal retina than the nasal retina because of the occurrence of the blind spot on the nasal side. The data are all average figures for two or three runs. Visual acuity is expressed in the decimal system instead of the commonly used acuity fractions. For comparison with the usual

20/20 or 6/6 notations, the decimal notation is merely the decimal conversion of these fractions.

Measurements of visual acuity less than 0.011 were not recorded, because the visual angle, and consequently the size of the retinal image, would be so large as to render such data meaningless in terms of a regional plot of visual acuity. A retinal area 1 degree in diameter is required to record a visual acuity of 0.083, and the error in retinal localization for this acuity may be considered to be 0.5 degrees. Similarly, if the acuity were as low as 0.0083, the retinal area concerned would be 10 degrees in diameter and the error 5 degrees.

For central fixation, acuity measurements could be made down to intensity levels as low as $5.6 \log \mu\text{l}$ (0.0004 ml.). Below this intensity, the center of the projected beam containing the image of the Landolt ring faded out. However, at $6.3 \log \mu\text{l}$ (0.002 ml.) the visual angle exceeded 1 degree, and the significance of measurements in this range as denoting central acuity is questionable. The data pertaining to this questionable range are enclosed in parentheses in Table 1. For determinations out to 4 degrees those involving visual angles greater than 2 degrees, and with implicit errors, therefore, of 1 degree in retinal localization, are also enclosed in parentheses. At 2 degrees, eccentric fixation acuity measurements could be made at intensity levels as low as $5.0 \log \mu\text{l}$; at 4 degrees, it was possible to make measurements as low as $4.3 \log \mu\text{l}$.

Retinal acuity contours are shown in Figure 1, where the curves for five light intensities are plotted. Only the data for the temporal half of the retina are shown; the nasal half showed fairly similar data, as can be seen in Table 1, with the exception that the apparent peak in scotopic acuity occurring at 4 degrees eccentric

fixation was not present. For the highest intensity level, the shape of the curve is quite similar to the previously recorded measurements of peripheral visual acuity. This is to be expected, since our highest μl , paracentral acuity exceeds foveal acuity. The acuity peak occurring at 4 degrees in the temporal retina persists throughout the intensity range from 7.6 to 4.9 log μl . In this range, therefore, it

Note: For all eccentric fixations along the horizontal meridian, the exposure time was one-fifth second; for central measurements, the exposure was of several seconds' duration.

intensity level was in the photopic range. At lower illuminations the central peak is not as precipitous, central acuity decreasing more rapidly than paracentral or peripheral acuity with diminution in light intensity. At intensity levels below 6.3 log would appear that fixation 4-degrees temporally to the object viewed affords maximum acuity. (In taking the Eastman Night-Vision Test and other tests involving scotopic form discrimination this subject had found that approximately this

fixation gave the best results.) At the lowest intensity levels, it can be seen that the contour is quite flat, visual acuity being almost constant from 4 degrees to 30 degrees.

Curves showing the relationship between visual acuity and light intensity for various areas in the temporal retina are shown in Figure 2. In order better to show the shapes of the curves, visual acuity as well as light intensity is plotted logarithmically. In order to avoid negative logarithmic designations, all acuity data are multiplied by 100 in this figure.

With central fixation and with eccentric fixations out to 30 degrees, the curves rise fairly steadily with increasing illumination, leveling off well in the photopic range. The maximum acuities diminish as the degree of eccentric fixation is increased. At 5 degrees a new phenomenon is quite evident: a distinct break occurs in the curve, indicating a division into a rod curve at the lower intensities and a cone curve at the higher intensities. A suggestion of this division into two component curves is seen at 4 degrees; the break is clearly evident at 7.5, 10, 15, and 20 degrees. It may be assumed, therefore, that sufficient rod cells are present in the retina at 4 and 5 degrees to dominate discriminatory function at intensity levels up to $8.0 \log \mu\text{l}$ (0.1 ml.), the intensity level at which the break occurs in the 4- and 5-degree curves.

Since, with central fixation, the test object was not discernible at intensity levels below $5.6 \log \mu\text{l}$, this intensity may be taken as the foveal light threshold. The light thresholds of the paracentral and peripheral cones vary only slightly from the central threshold. It is evident, therefore, that there is a wide range, up to $8.0 \log \mu\text{l}$, where the rod cells dominate the acuity process at 4 and 5 degrees eccentric fixation, despite the fact that cone cells

must be functioning. The reason for this is that the rod cells are functioning at their maximum efficiency at illuminations which are quite high for rod cells. The cone cells, on the other hand, are func-

Fig. 1 (Mandelbaum and Sloan). Visual acuity measured along the horizontal meridian of the temporal retina at five intensity levels ranging from 4.6 to 9.0 log micromicrolamberts. All eccentric measurements were made with $\frac{1}{2}$ second exposures; the central measurements were made with exposures of several seconds' duration. At 25 and 30 degrees all the curves except for 4.6 log micromicrolamberts practically run together, and are designated by single points.

tioning inefficiently at what is for them very poor illumination.

That there is such an overlap between cone and rod function, rather than an intensity level at which the rods cease to function and the cones begin to function,

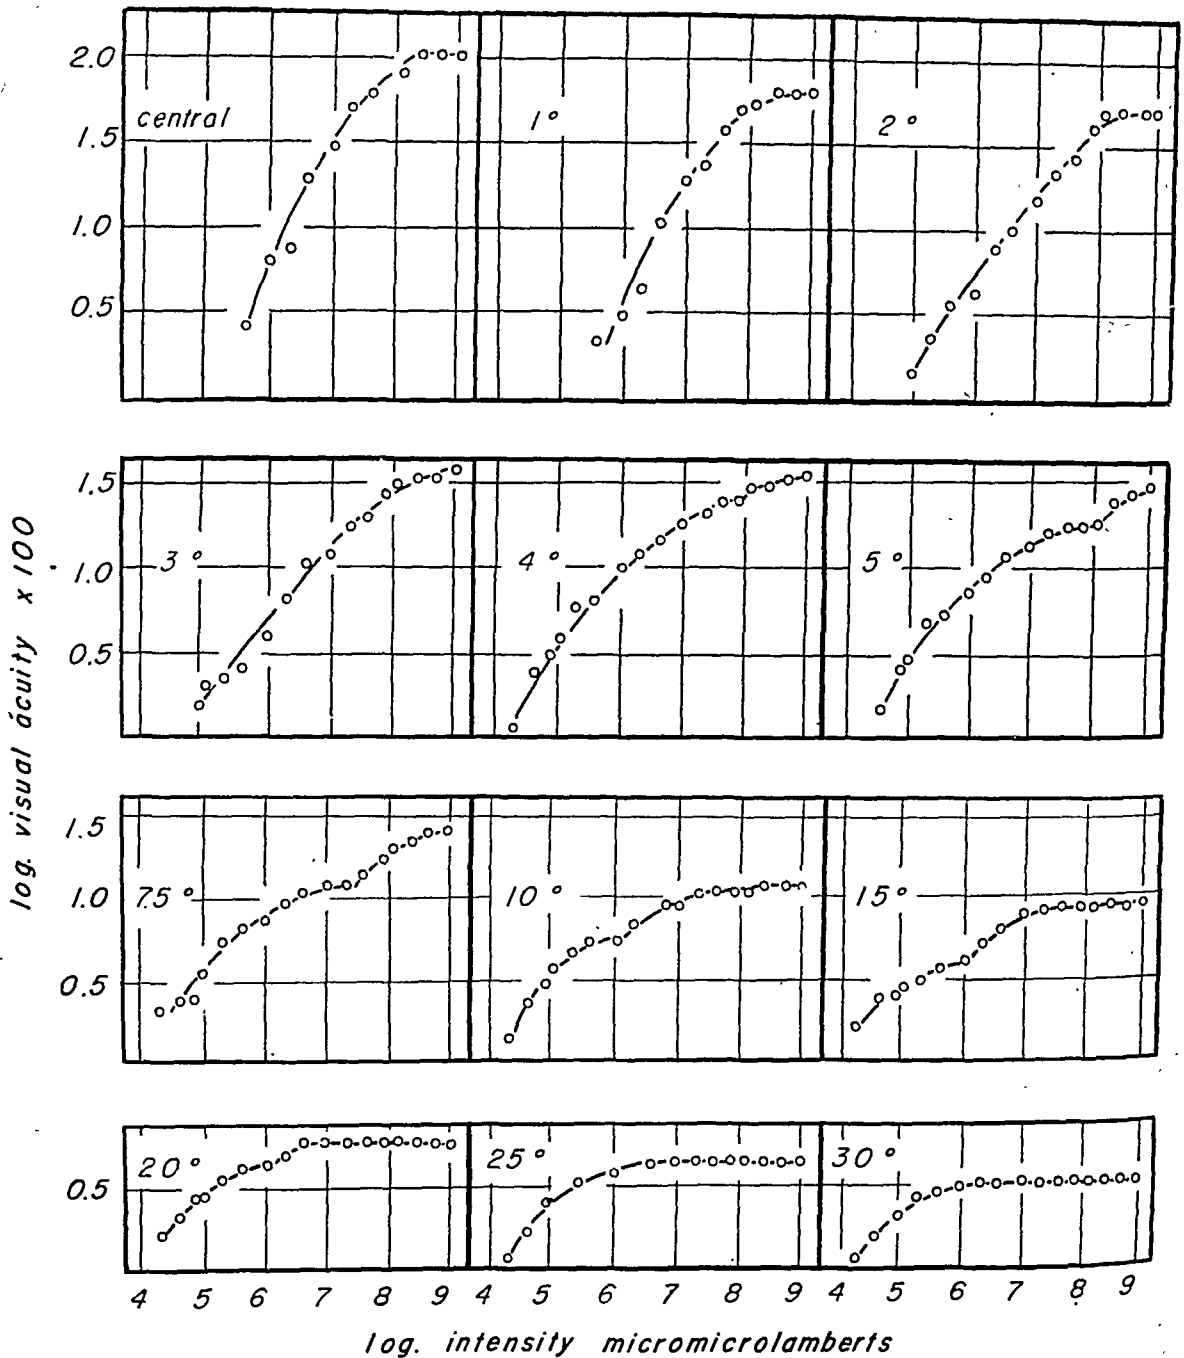

Fig. 2 (Mandelbaum and Sloan). Visual acuity curves for various locations in the temporal retina along the horizontal meridian. Visual acuity as well as light intensity is plotted logarithmically.

is to be expected from physiologic considerations, and can easily be demonstrated by other means. One of the easiest methods to demonstrate this is by viewing a spectral violet light after exposing one eye to a bright light while the other is

kept dark adapted.⁷ The intensity of the violet light should be approximately 1 millilambert. To the light-adapted eye, it will appear as a rich saturated color. The dark-adapted eye, however, will perceive a very pale, unsaturated color, because

here the cone sensation is diluted by the whiteness of rod sensation.

For 7.5-degrees eccentric fixation, the scotopic process dominates only to the intensity level $7.5 \log \mu\text{l}$; for 10, 15, and 20 degrees, the break is at approximately 6.0. This shift to lower intensity levels for the break between scotopic and photopic function, demonstrated in the curves as the eccentricity of fixation is increased, is probably related to the diminution in the resolving power of the more peripheral rods. The maximum acuity of the rod component of the curve for 4 degrees eccentric fixation, occurring at the intensity level $7.9 \log \mu\text{l}$, is 0.26 (as given in Table 1). For 5 degrees, it is 0.18; for 7.5 degrees, 0.11; at 20 degrees it is only 0.042, occurring at the intensity level $6.0 \log \mu\text{l}$. Because of this progressive diminution in rod resolving power, the cone cells take over the discriminatory function at lower intensity levels, closer to the cone light threshold.

As the fixation becomes more peripheral, the cone curve becomes less prominent. At 10 degrees the increase in visual acuity mediated by the cones appears to be from 0.050, the peak achieved by rod function, to 0.11. At 20 degrees, the increase is only from 0.042 to 0.058. At 25 and 30 degrees eccentric fixation, no cone curve at all can be made out, and only the rod curve remains. The contribution of the cone cells in this region to visual acuity seems to be of such poor order that they fail to exceed the efficiency of the rod cells, even at high levels of illumination.

It is evident from both Figure 1 and Figure 2 that the significance of illumination as a limiting factor in visual acuity diminishes considerably from the center to the periphery of the retina. When fixation is only 1-degree eccentric, visual acuity increases from 0.022 to 0.63 as the

light intensity is increased from 5.6 to $9.0 \log \mu\text{l}$. At 10 degrees the increase is only from 0.014 to 0.11 as the intensity is increased from 4.3 to 9.0, while at 30 degrees for a similar increase in intensity, acuity increases from 0.011 to 0.032.

Because of limitations in time, it was not possible to repeat these extensive measurements on more than one subject. Sufficient measurements were made on the eye of one other subject (J. M.) to confirm the general trend of the data given by L. L. S. In addition, binocular measurements were made on 18 subjects at an intensity level of $5.8 \log \mu\text{l}$, where the scotopic process dominates the picture. Maximum peripheral acuity for these subjects at the fixed intensity level was found to vary from 0.11 to 0.50, and occurred at retinal locations ranging from 4- to 8-degrees eccentric. Most of the subjects gave higher acuity readings when the fixation point was to the right of the test object; whether this has to do with the apparent superiority of the temporal retina and right-sided ocular dominance could not be determined. In three subjects vertical fixations were compared with horizontal ones; equally eccentric horizontal fixations gave approximately 10 percent better visual acuity.

CONCLUSIONS

1. Scotopic peripheral acuity does not parallel the rod population or the light sensitivity of the retina.

2. Maximum scotopic acuity can be achieved by 4- to 8-degrees eccentric fixation.

3. Light intensity is not as critical a factor in peripheral acuity as it is in central acuity.

4. At the lowest scotopic levels, visual acuity is fairly constant from 4-degrees to 30-degrees eccentric fixation.

5. A considerable overlap occurs between cone and rod function, the para-central rods dominating discriminatory function at light intensities well above the cone light threshold.

6. For 25- and 30-degrees eccentric

fixation, the rod cells dominate form discrimination even at intensity levels as high as 1 millilambert.

THE EFFECT OF ELECTRIC STIMULATION ON OCULAR TENSION*

P. B. ZARETSKAYA, M.D.

Moscow

The investigations of Prof. S. V. Kravkov and L. P. Galochkina demonstrated that the action of a weak galvanic current on the eye produces various changes in light and color perception. In view of these findings it seemed interesting to determine if stimulation with the galvanic current has any effect on ocular tension—a function which can be studied objectively. There were no data on this subject in the available literature.

Our method of investigation was as follows: The test person was adapted for 20 to 30 minutes to the usual daylight illumination of the laboratory. Tension was taken with the Schiøtz tonometer, after one instillation of 1-percent dicaine into the conjunctival sac. Then a galvanic current of 0.5 ma. was applied to the eye for 10 minutes. We used silver electrodes, wrapped in cotton moistened in physiologic saline solution. The positive electrode was applied at the temple close to the external canthus. The negative electrode was held in the opposite hand. Tension readings were taken at intervals of 4 to 5 minutes during galvanization. After the current was turned off, tension was recorded every 10 minutes for one hour. The test was performed in light adaptation and lasted about 90 minutes. The current was obtained from an accumulator, its intensity regulated by a rheostat and measured by a galvanometer. The tests were performed on six persons (mostly students).

Fundus and vision examination of these persons showed no deviation from nor-

mal with the exception of one case, which showed slight myopia. Altogether the following results are based on about 40 tests.

RESULTS

The results showed that galvanic stimulation in the intensity used produced noticeable changes in ocular tension. The changes were different, depending on whether the anode or the cathode was applied to the eye. Application of the anode to the eye invariably produced a reduction in tension from that found at the beginning of the test. There was no such constancy when the cathode was applied. In fact, in a number of cases hypertension was produced. Typical findings are illustrated in Figures 1 and 2. These graphs show the changes in tension recorded on different days for the same test person.

As may be seen from these charts, the tension curves are different after cathodic and anodal galvanization. The fluctuation in tension was more varied at the cathode (not infrequently varying 9 to 10 mm.) than at the anode. Reduction of tension at the anode was noticed in all curves. (In some cases the effect of the cathode was not so definite). Control tests were made, with the same set-up, but without galvanization of the eye. As may be seen from the curves no permanent changes in the tension were seen.

DISCUSSION

What are the processes leading to the changes in ocular tension herein described that are stimulated in the eye by action of the electric current? The mechanism of action of the galvanic current (cathelectrotonus and anelectrotonus) on the ocular tension is as yet not clear. It is pos-

Figs. 1 and 2 (Zaretskaya). The influence of a constant current on intraocular pressure. These graphs show the changes in ocular tension recorded on different days for the same test person. The lined column represents the time of galvanization on one day with the cathode, and on another day with the anode. A, identifies the test with the anode to the eyes. K, with the cathode.

sible that its effect on tension can be attributed to changes in the potassium-calcium balance.* These changes, according to the literature, take place during electrization of living tissue and may lead to profound changes in the metabolism of the cell.

It is interesting to mention in connection with our data Zondek's work, which shows that the physiologic action of po-

tassium is similar in effect to stimulation of the parasympathetic vagus nerve and that of calcium simulates the stimulation of the sympathetic.

Further investigation in this field may reveal that the reaction of intraocular pressure to electric stimulation may have diagnostic and, perhaps, therapeutic significance. Investigations on the effect of galvanism on intraocular pressure and on the pathogenesis of these phenomena will continue.

OCULAR MANIFESTATIONS OF MUMPS

A CASE OF MUMPS KERATITIS

JACK FIELDS, M.D.

Chicago

According to Parran,¹ mumps ranked next to venereal diseases as the most disabling of the acute infections among recruits of World War II. It is essentially a childhood disease. When present in young adults, the manifestations are much more serious. It has been estimated that in World War I, about four million man hours were lost by military personnel because of mumps. Statistics are not yet available on the manifestations and disability produced by mumps in this war.

In 1934,² the infectious agent of mumps was found to be a filterable virus. By injecting the saliva from patients in the early stages of the disease into Stenson's duct of monkeys, Johnson and Goodpasture were able to reproduce the disease. They were then able to reproduce the disease in human children by spraying the buccal mucosa and instilling into the nostrils the virus taken from the parotid glands of the monkeys.

The portal of entry of the mumps virus seems to be the nose and mouth,³ although Philibert⁴ believes that the portal of entry is possibly the conjunctiva with lodgement of the virus in the brain. When the virus is of low virulence, a slight and transient secondary reaction of the meninges occurs. When the virus is more active, clinical encephalitis is produced. He states that the virus is finally eliminated by the salivary glands.

Apparently the virus is transmitted by droplet infection upon direct contact. The incubation period is about 18 days, the disease becoming communicable about 24 hours before the onset of the first symptoms. One attack usually produces lifelong immunity. Both sexes are affected

equally. Mumps is endemic and can occur at any time, but the incidence is usually increased during the winter and spring. Mumps is now considered a systemic disease, probably a generalized infection of the blood stream through which the virus travels to reach the involved organs. No method of producing active immunity exists other than by acquiring the disease in its natural form.⁵ The varieties of extra-parotid manifestations may precede, accompany, or follow the onset of the parotitis.

Enders⁶ was interested in establishing a test for susceptibility so that in the event of an outbreak of mumps, a large number of nonsusceptible contacts would not have to be quarantined. He found antibodies in 92 percent of the sera of those giving a positive history of mumps, and in 50 percent of those giving a negative history. He concluded that one half of those giving a negative history may have had a silent infection at one time or another. Because the complement-fixation test was too laborious, that author sought another test to determine immunity and injected a diluted heat-inactivated suspension of infected parotid glands of monkeys intradermally. In nearly 100 percent of those giving a positive history of mumps, an erythematous reaction occurred after 24 to 48 hours at the site of injection. Enders concludes from the results obtained that a positive skin reaction indicates a previous infection with the virus; whereas, failure to react signifies, in most instances, potential susceptibility.

The council on Pharmacy and Chemistry,⁷ in its preliminary report, stated that human, convalescent, mumps serum

seems to be of therapeutic value in the hands of some investigators and induces some degree of passive immunity. Other investigators found the results less certain.

The recent work of Stokes⁸ and his co-workers on the use of formol-inactivated suspension of mumps virus as a vaccine against mumps is encouraging.

The manifestations of mumps in order of their frequency are: orchitis, oophoritis, pancreatitis, mastitis, and dacryoadenitis. Other less frequent manifestations are thyroiditis, bartholinitis, prostatitis, meningitis, encephalitis, and neuritis of the cranial nerves. The ocular manifestations are dacryoadenitis, conjunctivitis, scleritis, uveitis, keratitis, optic neuritis, retinitis, and ocular palsies.

OCULAR MANIFESTATIONS OF MUMPS

With our present knowledge of the pathogenesis of mumps, it is safe to assume that ocular manifestations may occur without any other signs or symptoms; therefore, a description of some of the more common ocular manifestations would not be out of place. Most textbooks on ophthalmology fail to mention all the manifestations of mumps. When they are mentioned, there is very little description of the clinical manifestations.

Villard⁹ believes that dacryoadenitis is the most common ocular manifestation of mumps. It is almost always bilateral, non-suppurative, and appears suddenly with sharp pains in the entire area of both orbits, radiating to the temples and forehead. Edema, especially in the external portions of the upper eyelids, and redness occur almost simultaneously with the onset of the pain. There is marked chemosis of the bulbar conjunctiva which usually herniates between the eyelids. The cornea is uninvolved. Palpation reveals a cartilaginouslike mass, generally elastic,

and painful in the region of the lacrimal glands. After several hours the symptoms begin to abate, with complete resolution of the inflammation of the glands in from several days to several weeks. Warm compresses is the only therapy advocated.

In the absence of any secretion, Villard states that mumps conjunctivitis is really a mild form of dacryoadenitis, involving the glandular acini present in the conjunctiva. Sendral¹⁰ reported a case of bilateral dacryoadenitis that preceded the onset of parotitis in a 10-year-old girl. This patient also developed mastitis and oophoritis. At first glance, a diagnosis of suppurative or gonorrheal conjunctivitis suggested itself until the lids were separated, and the absence of suppuration was noted.

There is no characteristic clinical picture of the iritis and iridocyclitis following mumps. All the cases reported cleared up without any sequelae, and were treated only locally with atropine.

Optic neuritis occurs in two forms; the retrobulbar type and neuroretinitis. In the retrobulbar type, complete recovery is the rule. In the neuroretinitic type, secondary optic atrophy may result. The retrobulbar type of neuritis is less common than the neuroretinitic type.

Young¹¹ reported a 10-year-old patient who showed optic neuritis with swelling of the nerve head 13 days after an attack of mumps. Vision dropped to nil following treatment with lactigen and mercurochrome, and then gradually returned to 6/6 (partly) in each eye. The visual fields were normal for a 10-mm., white test object. The nerve heads showed marked pallor.

Swab's¹² case of encephalitic optic neuritis resulted in postpapillitic atrophy of the nerve heads. Onset of the neuritis was 37 days after mumps for the right eye, and 46 days after mumps for the left eye.

Drainage of the spinal fluid was recommended as a therapeutic procedure by Hubbard. Powell and Dunlap¹³ reported two cases of optic neuritis with complete recovery. Case 1 occurred three weeks after the onset of the parotitis. There was questionable vision in each eye. Following the use of artificial-fever and foreign-protein therapy, vision in each eye returned to normal five months after the onset. The second patient who developed visual difficulties, one month after an attack of mumps, also had a paralysis of accommodation. The visual acuity, accommodation, and visual fields gradually improved to normal. These authors emphasize the necessity of investigating cases of visual disturbances following mumps.

Butler and Wilson¹⁴ observed two cases of ocular paralysis following mumps. The first patient was a nine-year-old boy with complete paralysis of accommodation following an attack of mumps three weeks earlier. Recovery was complete. The second patient was a 12-year-old boy who had mumps 30 days before the onset of a complete third-nerve paralysis of the left eye. Two days later the external rectus became paralyzed. The superior oblique did not become involved. Eight months later, internal ophthalmoplegia and paralysis of elevation were still present, along with a slight weakness of convergence and abduction.

KERATITIS DUE TO MUMPS

Keratitis due to mumps is exceedingly rare. Villard⁹ collected only three cases from the literature, two of which were ulcerative, healing with a central leukoma and producing a marked diminution of vision. The third case was an interstitial type of keratitis with complete recovery.

Danielson and Long¹⁵ were able to find

only seven cases of mumps keratitis in the entire literature, and added one case of their own. So uniform was the clinical appearance of the cases reported, that the authors considered mumps keratitis a definite clinical entity. The onset usually occurs with redness of the bulb and lacrimation from about 2 to 11 days after the onset of the parotitis. Pain is very slight or absent. Within a few days, a diffuse keratitis develops, producing a marked clouding of the cornea. Marked reduction of vision follows. The pupil reacts to light, and also dilates maximally with atropine. Uveitis or synechias have not been observed. Vascularization of the cornea is absent, and complete recovery with unimpaired vision occurs in from one to four weeks. All cases have been unilateral, either eye being involved. Lippmann¹⁶ added another case of mumps keratitis making a total of nine known cases. The rapid onset of the opacity, involving the entire cornea, which reaches a high degree of density with corresponding loss of vision and shows complete clearing without scar formation, has been stressed by him as differential diagnostic signs.

To help establish mumps keratitis as a definite clinical entity, I wish to report a 10th case.

CASE REPORT

HISTORY

P. E. L., an aviation cadet, aged 26 years, was admitted to an army hospital on July 27, 1943, complaining of pain and swelling in both parotid regions of two days' duration associated with some malaise. On the day of admission, a burning sensation of the right eye and blurred vision were experienced. Examination by the ward surgeon revealed a conjunctival injection with some apparent cloudiness of the right cornea, and a bilateral, somewhat tender swelling of the parotid

glands. Two days after admission, I was called to see the patient, who then complained of some pain, photophobia, and lacrimation in the right eye associated with marked reduction of vision, all of two days' duration. Vision was limited to hand movements at two feet in the right eye, and was 20/20 in the left eye.

OCULAR EXAMINATION

Examination of the right eye revealed a two-plus, mixed injection of the bulbar conjunctiva. The cornea was uniformly hazy, giving it a milky appearance. It did not stain with fluorescein. With loupe magnification and oblique illumination, deep interlacing linear opacities could be made out. Descemet's membrane showed some folds. The anterior chamber and iris appeared normal. The pupil did not appear irregular nor did it differ in size or reaction to light from its fellow.

Further ocular examination was accomplished at the eye clinic to which the patient was brought after proper facial draping to prevent the spread of the mumps. Slitlamp examination revealed normal surface epithelium. The linear opacities were localized in the substantia propria, most numerous in the posterior one third. Definite wrinkling of Descemet's was present. There were no keratic precipitates. Vascularization, either superficial or deep, was absent. Fundus details could not be made out. The left eye was entirely normal. The diagnosis was acute keratitis complicating epidemic parotitis. Hot compresses were applied, and a 1-percent atropine solution was instilled 3 times daily. The pupil dilated readily with atropine. It was noted that the dilatation was maximal and that the pupil was uniformly round.

COURSE OF THE DISEASE

The next day, July 30th, the cornea was still diffusely hazy, but there was definite clearing at the periphery. There was no change in the intensity of the bulbar injection. The pupil was widely dilated. The same treatment was continued. Inspection of the right eye 24 hours later showed marked improvement, the opacity being now limited only to the central portion of the cornea. The injection of the bulb had also decreased. Because of the rapid clearing of the corneal opacity, the use of intravenous typhoid was withheld. Clearing of the remainder of the cornea continued steadily. On August 5th, nine days after the onset, the eyeball appeared perfectly white; the cornea was entirely transparent and was essentially negative to slitlamp examination. Vision was 20/20. Further medication was discontinued. The patient was discharged back to duty on August 10th, at which time another ocular examination was made on the right eye. All findings were normal.

CONCLUSION

Mumps is now considered to be a systemic virus disease which affects the various organs through the blood stream. The ocular, as well as some of the systemic, manifestations may precede, follow, or accompany the onset of the parotitis.

Keratitis, the rarest of all ocular manifestations of mumps, is a definite clinical entity as established by the similarity in the onset, clinical appearance, and course of the nine cases previously reported, and the one just added by me. The term, Mumps Keratitis, is advocated.

PRIMARY GLAUCOMA AND THE PITUITARY-DIENCEPHALIC SYSTEM*

HERMAN ZONDEK, M.D., AND GERDA WOLFSOHN, M.D.
Jerusalem, Palestine

It is a well-known fact that in many respects knowledge of the pathogenesis of primary glaucoma is still vague. Among other causes, endocrine factors are believed to be responsible for its occurrence—thyroid,¹ pituitary,² cortico-adrenal system,³ and gonads.⁴ In recent years we have had the opportunity of examining 22 cases of primary glaucoma which were referred to us for internal examination with the view that there might be a possible connection between the ocular condition in these cases and the diencephalon or pituitary-diencephalic system. Such a relationship has already been established between other ocular diseases and the pituitary body or the diencephalic-pituitary system (retinitis pigmentosa, Zondek and Koehler⁵ and Zondek and Wolfsohn;⁶ the Lawrence-Moon-Biedl syndrome; and pituitary-diencephalic exophthalmos, L. P. Daniels,⁷ Zondek and Ticho⁸). We made tests of the carbohydrate and water metabolism, basal metabolism, blood cholesterol, and the osseous structure of the skull. A few characteristic cases will be reported in brief.

CASE REPORTS

Case 1: C. S., aged 15 years, gave the history that his mother was suffering from primary glaucoma (case 2). Although he had just been seen by an oculist who found increased ocular tension, the patient made no complaints. He was very tall—just over six feet—with a moonlike face. Pubic and axillary hair growths were normal. There was no facial hair growth. Visceral organs were nor-

mal. Blood pressure was 95/70 mm. Hg.

Laboratory findings showed: blood count and urinalysis, negative. Glucose-tolerance test at half-hour intervals showed: 122, 118, 100, 107, 90, and 114 mg. percent (hyperinsulinic curve). Volhard test: after having drunk 1,000 cc. water, the patient voided 800 cc. urine within the next two hours. X-ray studies showed the sella turcica to be normal; the skull to be extremely rarefied, and the galea to have an appearance almost like cotton wool; thus, giving an impression of the beginning stages of Paget's disease of the bone. The eyes showed primary glaucoma.

Case 2. Mrs. E. S., aged 39 years, was the mother of the boy in Case 1. She had had a rather large goiter since childhood. For the past few years, the patient had seen rings in front of her eyes. Her voice was said to have grown hoarse and deep lately. She had a tendency toward pronounced oscillations in weight; for example, gain in weight had been 17 to 18 pounds in the last month. She was subject to moods of depression accompanied by voracious hunger and feelings of anxiety. She was masculine in type and showed hirsutism. She had a rather large parenchymatous goiter.

Examination on admission to the hospital showed the visceral organs to be normal. Blood pressure was 110/70 mm. Hg. Urinalysis and blood count were normal. Glucose-tolerance test at half-hour intervals showed: 80, 142, 117, 107, 96, and 75 mg. percent; glycosuria occurred at the time of the second and third readings. A second glucose-tolerance test at half-hour intervals gave this reading: 80, 117, 80, 62, 78, and 67 mg. percent; gly-

* From the Department of Internal Medicine, Bicur Cholim Hospital.

cosuria occurred at the time of the second, third, and fourth readings (traces, 1 percent, and traces). The sella turcica was widened in the anterior-posterior diameter. There were vascular furrows in the skull. Blood cholesterol showed 266 mg. percent. The basal-metabolism rate was a minus five. The eyes showed primary glaucoma.

Case 3. Mrs. S. L., aged 42 years, in giving the family history said that three brothers and three sisters out of nine siblings were suffering from glaucoma. She had had four operations for glaucoma, one on the right eye and three on the left eye. Glaucoma attacks occurred just before menstruation, which is regular. She had always been fat, and during the past months had been gaining. She suffered from migrainelike headaches.

On admission to the hospital, her weight was 191.4 lbs. She had a moon-like face. Striae were not present. The pulse rate was 60. Blood pressure was 120/80 mm. Hg. The visceral organs were normal. Urinalysis and blood count were normal. The glucose-tolerance test was: 68, 129, 120, 118, 169, and 230 mg. percent; no glycosuria. The Volhard test was normal. Basal-metabolism rate was a plus 29. Ten days after menstruation there were 500 mu of estrone in the urine. The sella turcica was of normal size and shape. There were increased vascular furrows in the skull. The ocular findings showed primary glaucoma.

Case 4. Mrs. L. R. had suffered from migraine since childhood. Menstruation was somewhat irregular, and she had always been moderately fat.

Examination on admission to the hospital showed moderate obesity. The visceral organs were normal. Blood pressure measured 125/70 mm. Hg. Urinalysis and blood count were normal. Readings at half-hour intervals in the glucose-tolerance test were: 117, 145, 121, 138, 110,

and 163 mg. percent (diabetic type); no glycosuria. Two blood-cholesterol readings were: 350 mg. percent and 266 mg. percent. The Volhard test showed: after drinking 1,000 cc. of water, the patient eliminated 1,220 cc. of urine within the following two hours. The basal-metabolism rate was a plus two. X-ray studies of the skull showed the posterior clinoid processes to be poorly defined. There were increased vascular furrows in the skull and extreme rarefaction of the osseous structure. The eyes showed primary glaucoma.

Case 5. Miss E. N., aged 30 years, had a negative family history. For several years, there had been a progressive enlargement of the prominent parts of the patient's body—nose, lips, tongue, hands, feet, and so forth. She had been suffering from an increasing number of headaches. Menstruation had become irregular and then had ceased entirely about a year earlier. About three years before, the patient had had X-ray irradiation of the pituitary gland. A few months after this, her vision became worse and she complained of green rings in front of her eyes. She was treated with pilocarpine and eserine. She is subject to moods of depression.

Upon admission to the hospital, she showed obesity. Her face was puffy and had a bluish-red tint. Her lips were thickened, and her tongue, feet, and hands enlarged. Her voice was hoarse. The pulse rate was 60 to 72. Blood-pressure reading was 140/70 mm. Hg. With the exception of the heart, which was enlarged to the left and gave dull sounds, the visceral organs were normal. The tendon reflexes were sluggish.

Laboratory findings gave the following results. Blood count and urinalysis were normal. The glucose-tolerance-test readings were: 98, 110, 120, 134, 116, 134, and 134 mg. percent. Blood cholesterol showed

169 mg. percent. In the Volhard test, after the intake of 1,000 cc. of water, 320 cc. of urine were eliminated in the following four hours. The basal-metabolism rate was a plus 16. Electrocardiogram readings were normal. There was an enlarged sella turcica, unilaterally excavated; the galea was very thick; there were increased vascular furrows in the skull (pituitary tumor). The eyes showed primary glaucoma.

Case 6. Mrs. F. S., aged 62 years, gave a negative family history, and her previous history was irrelevant.

Examination upon admission to the hospital showed obesity. She had cyanotic lips. Her pulse rate was 106. The blood-pressure reading was 190/110 mm. Hg. The visceral organs were normal, the heart and aorta were not enlarged. Urinalysis and blood count were normal. Readings for the glucose-tolerance test were: 115, 181, 203, 206, 225, and 181 mg. percent; glycosuria was present at the time of the fourth, fifth, and sixth readings (1, 2, and 3.4 percent). The Volhard test was normal. Blood cholesterol was 308 mg. percent. The basal-metabolism rate was plus 18. An X-ray film of the skull showed a pituitary tumor which had penetrated into the sphenoid sinus. Ocular examination showed primary glaucoma in the right eye.

Case 7. Miss B. N., aged 45 years, said that her mother had glaucoma. The patient was first seen by us seven years ago. At that time, she said that menstruation had ceased about one year earlier. Her hands and feet had grown larger, and her face had coarsened. She complained of splitting headaches and was subject to moods of depression. Five years ago, X-ray irradiation of the pituitary gland caused the headaches to subside. After the lapse of a year, however, the patient began to see rings in front of her eyes. Following this symptom, a diagnosis of glaucoma was made. Since then she has

been under the constant care of oculists.

Examination at this time showed her to be of the acromegalic type. She had enlarged hands, feet, lips, and tongue; her arms and legs were bulky. With the exception of a slightly enlarged left ventricle of the heart, the visceral organs were normal. Blood pressure showed 120/80 mm. Hg. Apart from traces of albumin, the urinalysis was negative. Blood count was normal. Glucose-tolerance test showed: 111, 151, 118, 125, 129, 111, and 117 mg. percent. Blood cholesterol measured 262 mg. percent. In the Volhard test, after the intake of 500 cc. water, 80 cc. urine were voided within the following four hours. The basal-metabolism rate was a minus two. There was bone atrophy around the sella turcica, which was uniformly enlarged. There was marked vascular congestion. The eyes showed primary glaucoma.

DISCUSSION

Among the 22 cases of primary glaucoma studied, 16 cases gave various combinations of evidence which pointed to disturbances in the pituitary-diencephalic system. Obesity, menstrual troubles, disordered carbohydrate metabolism, a tendency toward water retention, deviations of the basal-metabolism rate from the normal average, decalcification or atrophy of the bony skull (particularly around the sella turcica), occasionally calcification also, congestion of the meningeal vessels, and a rise in blood cholesterol were among the signs noted.

It should be emphasized that abnormally high blood-cholesterol values were frequently found in processes localized in the pituitary-diencephalic region (Zondek and Ticho⁸).*

It is noteworthy, too, that pitui-

* The author has recently learned that Schmelzer also reported upon the rise in blood cholesterol in cases of primary glaucoma (Med. Welt, 1943, v. 44 and 45, p. 779).

tary tumors were present in 6 of these 16 cases, and that two of the patients with pituitary tumors presented the characteristics of acromegaly. In 6 cases out of our total number of 22 cases, there was no evidence of any pituitary-diencephalic disturbances. This fact may indicate that the pathogenesis of primary glaucoma cannot be viewed from a common aspect. On the other hand, it is impossible to ignore the findings established in the majority of our cases.

It would appear from previous investigations—at least in a number of cases of primary glaucoma—that two etiologic factors are of special importance:

1. Abnormal vascular function.
2. Hydration of the corpus-vitreum tissues.

In abnormal vascular function, both the abnormal narrowing (spasm and sclerosis) of the afferent vessels of Schlemm's canal (according to Friedenwald⁹ this delays the flow of blood through the canal and causes a decrease in water-reabsorption rate) and abnormal dilatation of the vessels (this causes an increase of vascular permeability and, therefore, an increase of intraocular fluid) play an important part.

It might be added that the lowering of intraocular pressure in diabetic coma, a condition known to be associated with dehydration, may be considered as a proof for the role played by the ocular fluid content in regulating ocular tension. Both abnormal circulation and the tendency toward tissue hydration may well be explained by disordered pituitary function. It is up to future research to demonstrate whether, and how, antidiuretic hormones can get into the eye.

In 1935, one of us (H. Z.¹⁰) reported upon a syndrome for which the term "diencephalopathy" was suggested. This syndrome not only comprises certain metabolic disturbances pointing to the diencephalon but also changes in the osseous

structure of the skull (either abnormal calcification or abnormal decalcification), psychic anomalies, and ocular disorders (retinitis pigmentosa).

Recently Zondek and Ticho⁸ showed that some types of exophthalmos are probably of pituitary-diencephalic origin. Even before this work was published, other authors had drawn attention to the possible part played by the thyrotropic factor of the anterior lobe in the genesis of this disease. Among the etiologic factors in this type of exophthalmos, hydration and edema of the external ocular muscles are known to be of importance. The assumption that the antidiuretic factor of the posterior pituitary lobe may be responsible for the occurrence of local water retention does not, therefore, appear to be far fetched.

It is not unreasonable to assume that both pituitary-diencephalic exophthalmos (as designated by Zondek and Ticho) and some types of primary glaucoma may be included under the heading "diencephalopathy." At least, this assumption is not unreasonable in so far as anomalies of circulation or of water-salt metabolism may result in different clinical manifestations in the eye. As with exophthalmos, it should be possible to define certain types of primary glaucoma as "pituitary-diencephalic glaucoma."

The fact that the origin of a number of cases of primary glaucoma can be traced to tissue hydration (corpus vitreum) points to the therapeutic effect of dehydrating measures. It may be assumed that the beneficial effect of thyroidin recorded by Hertel¹ is to be thus interpreted. A few patients to whom we have given mercurial diuretics have stated that they have had at least subjective relief. This hint should be checked by oculists, since it may serve as a supporting measure in situations in which acute action on the increased intraocular pressure is required.

SUMMARY

Sixteen out of 22 cases of primary glaucoma showed, in varying degrees, changes which pointed to the pituitary-diencephalic system. Six of these 16 cases presented pituitary tumors. No pathologic findings could be obtained in 6 of the 22 cases. The question as to how far pituitary hormones (particularly of the posterior lobe) or pituitary-diencephalic factors are to be held responsible for the oc-

currence of primary glaucoma is discussed. "Pituitary-diencephalic" glaucoma is the term suggested to designate those cases of primary glaucoma which exhibit the pituitary-diencephalic symptoms herein described. Such a definition would be analogous to that for the syndrome of pituitary-diencephalic exophthalmos.

THE PSYCHOLOGY OF THE SQUINTER*

ANN E. STROMBERG

Baltimore, Maryland

Although this paper is entitled "The Psychology of the Squinter," it deals mainly with the psychology of the orthoptic treatment of the squinter, and this might be a more appropriate title.

Much has been written on child psychology with emphasis on the psychology of the handicapped and exceptional child. Certainly, I can add nothing to what is already in the literature concerning the psychology of squinters, but I can emphasize the main characteristics of the squinter, and the psychology which should be used by the technician, the parents, and the teacher.

Orthoptics is defined as a method of teaching or restoring binocular single vision by means of graded exercises. It is an educational process, just as much as teaching mathematics is an educational process. To be successful, any teacher must understand something of the psychology of her pupils as individuals. Binocular single vision is a high degree of skill, and if we are to teach it successfully, we must realize that our pupils are individuals with many complex psychologic problems which can, to a great extent, account for their trouble.

Our aim is to obtain a cosmetic and a functional cure; that is, the patient's eyes must not only look straight, but he must have comfortable single binocular vision which he can use in daily tasks. Anything less than this is, strictly speaking, an orthoptic failure. However, to quote Dr. Costenbader: "A lesser grade of cure is better than a cross-eyed child. We should pick the cases for prolonged

orthoptics in which there is the greatest chance for a true cure, and make the other patients happy by simply making them look better."

We must always remember that we are treating individuals and not just a pair of eyes, a convergence excess, or a case of amblyopia ex anopsia. Each patient is an individual problem, a challenge; no two are just alike. It would be simple to classify each patient as to his type of squint and treat him according to a set rule, one step following another. By observing and treating many patients, it is true that it has been possible to establish a pattern of technique for treating each type of squint, but the individual squinter will achieve each skill in his own way. We must first understand the difficulty of the individual and base treatment along those lines best suited to him, in order for him to achieve his goal of comfortable binocular single vision.

Very few young squinters ever complain of visual confusion. They may alternate the fixation, suppress the vision of one eye entirely, or develop anomalous retinal correspondence, and still experience no ocular discomfort. Until they reach the age when the lack of binocular single vision is felt, or until they are made aware that they have crossed eyes, they are quite happy.

The squinting person, child or adult, is as physically handicapped as one who must wear braces or use crutches. The squinter becomes aware that he looks different from others as soon as he comes in contact with children of his own age, usually when he starts to school. It is now customary for children to enter nursery school at two or three years of age. Fortunately, at this age, they are usually very

* Read at the meeting of the American Association of Orthoptic Technicians at Chicago, October 14, 1946.

self-centered, and not observant or critical of one another's appearance. Personal pleasure is their main interest in life. For this reason, the advisability of straightening a child's eyes before he reaches school age cannot be too strongly emphasized. If at the age of six he can start his social contacts with other children with straight eyes, he is spared much unnecessary suffering. The infant squinter, if he is wearing a patch, is usually impervious to the glances and comments on his unusual appearance. One mother told me that she had never realized there were so many thoughtless people in the world until her child wore a patch. Few would ever think of mentioning a deformed limb or a disfiguring mark to the unfortunate possessor or to his sensitive parents, but on seeing a child with a patch, curiosity overcomes them and they want to know if the child is blind in one eye, or how he hurt it. The majority of young squinters are very nervous and sensitive, and these well-meant inquiries make them more conscious of their eyes. The young squinter can be spared a great deal of heartache if he can start to school with his eyes at least cosmetically straight and with his period of occlusion, if that is necessary, behind him.

There is not a great deal that one can do for the infant squinter with orthoptics beyond diagnosing the type of squint and occluding, if that is necessary. His mind is not yet ready for the concentration and will to learn that are absolutely necessary for successful fusion training. If we are to accomplish anything with him, it must be in the guise of play.

The first few visits of the infant squinter are spent in becoming acquainted with him and in convincing him that he is in friendly hands; that he is not going to be hurt. It is usually possible to obtain enough information to determine the type of squint and what treatment: surgery or

orthoptics—or both—will be needed. We can get a fairly accurate idea of the vision with the illiterate "E" chart, picture charts, or the Bailey test. A young child always likes to hold a light and look at it through red and green glasses. We can get a prism and cover measurement fairly accurately, if it is done quickly. In the same way, it is also possible to determine the fixing eye, and get a rough idea of the ocular motility. The child always likes to see the movies, and we can get an objective setting, at least, if the flashing is done very quickly. However, no matter how enthusiastic and coöperative the child is, if he is less than four years old, it is impossible for him to concentrate on one target for more than a few seconds. He simply lacks the power of concentration that comes when he is a little older.

A four-year-old accommodative squinter can be taught to hold his eyes straight but only if he is an exceptionally bright child. Any attempt to force his undeveloped concentration is likely to result in a serious emotional upset and cause him to nourish a deep-seated hatred for any form of eye exercises, which will make it impossible to obtain future coöperation, even though he will then be old enough to learn binocular single vision. At six years, the child has developed some ability to reason. Then, success lies in making him want binocular single vision. Although he is capable of learning to hold his eyes straight in daily tasks, he will never be able to do it unless he desires straight eyes and is willing to work to achieve that goal.

GROUPS OF SQUINTERS

Squinters can be divided into four groups:

1. Can the patient straighten his eyes? If not, then orthoptic training is useless as the error is anatomic and can be corrected only by surgery. After the eyes have been set reasonably straight, post-

operative fusion training can be started.

2. Can the patient recognize his errors? Binocular single vision is certainly a very difficult skill to learn, and it stands to reason that a child with very low intelligence is not capable of learning it. He must understand what is required of him, in order to carry out even the simplest of exercises.

3. Can the patient be comfortable while holding his eyes straight? If he can fuse, but his imbalance is such that fusion is always a distinct effort, he will not use it for casual seeing. In cases such as this, surgery combined with orthoptics gives the best results. In every case, the patient must have comfortable visual habits. If he is not comfortable with binocular single vision, he will revert to his old, incorrect habits of seeing.

4. Does the patient want to use his eyes correctly? Every squinter who has been successfully cured with orthoptics belongs in this class. Without a strong desire for straight eyes, and a determination to have them, sufficient coöperation to effect an orthoptic cure cannot be obtained. Fusion has been defined as the satisfaction of a desire for a single image. If fusion failed to develop spontaneously, the patient must desire it, in order to obtain it. A child must have reached the age of readiness for learning binocular single vision before he can do so. He must have reached the age of readiness for learning any particular skill, if he is to achieve it. Most children start to grade school at the age of six because that is the usual age of readiness for organized learning. It is also the age at which he becomes aware of other people and begins to care what others think of him.

SIX-YEAR-OLD SQUINTERS

The unfortunate child who has to attend school with a noticeable squint or wears an unsightly patch has a great deal

of self-adjusting to do. He is usually oversensitive and high strung. At the age of six, a child is not able to reason that he is just as capable as others, although he does not look like them. His mental development is not sufficient to make him consider the feelings of others less fortunate than himself. The squinter has to bear taunts of "cross eyed," "four eyes," if he has to wear glasses, and many other equally uncomplimentary names. Because of poor vision, he may fall behind in his school work.

Reading is a new and highly difficult skill that he must learn, and one which will be important to him in everything that he does. It requires good binocular coördination of the eyes, and so the squinter is off to a very poor start. He is often a poor athlete and socially he is, perhaps, an outcast because of his appearance. His teacher may fail to understand his plight and keep him in a seat where he cannot see the blackboard or chide him before the class for his slowness in reading or copying his work.

All of these impressions are deep and lasting in a child of this age, for it is at this time that he is very sensitive to the attitude of others. These are his formative years, and during this time he develops into a useful, well-adjusted citizen, or into a psychologic problem. He may develop a deep sense of his own inferiority. Although he may never say anything about it, he feels left out of things and is forced to take a defensive attitude to cope with the situation. He becomes either excessively shy and timid, or he goes to the other extreme and becomes overaggressive. His is the loudest voice in any argument. He bullies younger and smaller children, and is generally a problem both at school and at home.

It follows, therefore, that we not only have to deal with a squint, but sometimes a serious emotional problem as well. If he

has a very noticeable squint, cosmetic straightening of his eyes will produce a marked improvement in his emotional stability. There is always a great change in the attitude of the patient, child or adult, when his eyes have been set cosmetically straight. He at least looks like everyone else, even though he may not have learned to use his eyes correctly. His school work improves and so does his general outlook on life.

If a child is very sensitive about his appearance, he is usually coöperative when he understands that the goal of all of his effort is straight eyes. This desire for straight eyes is sometimes very difficult to inspire in a young child. Usually the best method of obtaining coöperation is to ask him what he wants to be when he grows up, and, no matter what the answer, tell him that to achieve his wish is impossible unless he has straight eyes and uses them together.

KEEPING THE CHILD INTERESTED

Keeping the young patient interested over a long period of training is a more difficult task. He may be enthusiastic at the start, but he is quickly bored if the goal toward which he is working is very distant. I think that praise for each task accomplished does more to uphold his interest than anything else. The future is very distant to a child of grade-school age. He lives for today, and praise for today's work means much more to him than glowing accounts of what he will be able to do in six months. He must be praised for each achievement. Any task given him must be within his ocular and mental capacity or he will be quickly discouraged.

Most children are anxious to please and some will agree to anything. It is soon possible to tell which child lacks the desire to improve to the extent that he is willing to make things easier for himself by giving untruthful answers. He must be made

to understand that he is the one who must do all of the work, and that wrong answers are of no help.

Rewards of any kind are excellent for maintaining coöperation, if they are given only when they are deserved. If the patient does not put forth the effort expected of him, he should have no reward. Some technicians use report cards. At each visit the child receives a star which he is allowed to put on the card. It is gold if he has done excellent work, silver for good work, red, blue, green and so on, down to no star at all for poor attention. He is allowed to choose the star he thinks his application has merited and is usually honest enough to choose the right one. This seems to be an excellent method of maintaining the coöperation and enthusiasm of young children. They are very proud of any stars or report cards received in school, and if the squinter is not doing too well in his regular school work, the stars he receives for doing his exercises well are very welcome. I have a large screen, and each coöperative patient is allowed to draw a picture and hang it there. If he does not give the proper attention to his work, the picture goes home with him. Some technicians use candy as a reward. No matter what the reward, if a child is denied it for poor coöperation, he will usually try to improve at the next visit. Rewards are not absolutely necessary, but they are a great help with many children, when nothing else seems to inspire effort.

In spite of everything we can do, there are times when a child will no longer coöperate, even though he has shown some improvement. He is too conscious of his eyes, and tired of exercises. The best thing for him is a vacation. Let him forget his eyes, and he will come back with a renewed desire to improve.

ATTITUDE OF PARENTS

The attitude of the parents is most im-

portant in the treatment of a squinting child. Complete coöperation on the part of the parents or guardian is the first requisite for successful orthoptic training for children. If the parents understand what is wrong with their child, they are usually willing to do almost anything to help him. The ophthalmologist and orthoptist can explain, in terms which will be easily understood, the results of their tests and what they propose to do. The parents of a squinter must understand his difficulty and allow for his difference from his brothers and sisters. If they are to help their child, however, they must overcome the tendency to defer to all of his wishes to the extent of spoiling him. Mother can do a great deal in making Johnny understand that he must wear his patch. She can encourage him and make his home exercises a game instead of a dreaded task. The squinter who has a happy, well-adjusted home life, with wise and understanding parents, will achieve his goal in a much shorter time than the one who hears constant nagging about his exercises and criticism instead of praise at home.

THE PSYCHOLOGY OF PATCHING

The psychologic aspects of patching deserve special mention. Unfortunately, it is very often an absolute necessity in the treatment of squint. Here again, the desirability of treatment during the pre-school years is evident. Occlusion seldom has an adverse psychologic effect on a two- or three-year-old child. Once he has become accustomed to wearing the patch, he forgets all about it. He must understand, however, that the patch must stay on at all times. Here the coöperation of the mother is most important. If she is firm at the start of the occlusion period, she will have no trouble, but if she lets the child remove his patch at various times, she will find that he is a problem.

When a child reaches school age, patching presents a more difficult problem. He may have difficulty in making friends, or fall behind in his work. He fails at many things and, if not handled properly, develops a genuine feeling of inferiority which produces a kind of paralysis of effort.

After the age of 11 or 12 years, a child may develop such a severe complex that the results of patching are not worth the psychologic havoc which may be wrought. At this age, too, the probability that occlusion will improve vision to any great extent is much more doubtful.

To make a success of occlusion, the patient must be sold on the idea, except in the case of a very young child. We must appeal to his pride, to his future ambitions, or to his vanity to make him understand the value of two good eyes.

We all have to cope with the problem of peeking over, under, or around the patch. Many children mean well, and make solemn promises not to peek, but do so anyhow. The most successful method of avoiding this would seem to be by having patches which exclude all light from the eye. If the vision of the amblyopic eye is so poor that his activities are greatly limited, it is almost impossible for a child not to try to use the occluded eye if it is at all possible. Any child who persists in peeking when he is wearing an Elastoplast patch, is not sold on the idea, and probably will not improve unless his attitude is changed.

Constant encouragement makes the period of occlusion easier for both patient and parents. Any improvement, no matter how small, is welcomed; and for this reason, it is well to check the vision of the patient frequently, especially when he first starts to wear his patch. It is well, too, to be able to show the parents that the occluded eye still has good vision, for they invariably worry about it. The child

thrives on praise for any tasks which he can accomplish well, and accepts extra help with those tasks causing difficulty. Praise, instead of criticism, will help him more than anything else.

As the patient grows older, chances of a marked improvement of the vision in his amblyopic eye decrease. This should be carefully explained to him, and he should be allowed to make the choice of whether or not to wear a patch. If he has a goal which requires equal vision in his two eyes—the Naval Academy, West Point, and so forth—he will try anything to regain his vision.

SUMMARY

The success of orthoptic training de-

pends on the desire and will of the patient to learn the skill of binocular single vision. The development of this will to succeed depends largely on the teaching ability of the orthoptist. She must present exercises in the way that will be most readily accomplished by each patient. She must analyze the problem of each patient and find out what can be done with a maximum of effort. Then the patient's desire for success must be stimulated. As soon as he has learned one skill, he should start immediately to learn the next. Above all, we must think of our patients as individuals, not cases. We must never forget the human element involved.

NOTES, CASES, INSTRUMENTS

HEMORRHAGE IN SARCOMA OF THE CHOROID*

A CLINICAL PATHOLOGIC REPORT

JOSEPH LAVAL, M.D.

New York

HISTORY

H. M., a 55-year-old white man, had noticed for the past two weeks an occasional "shadow" in front of his left eye which he thought might be caused by his heavy, bushy eyebrows. He often tried to brush it away but it recurred frequently. On the day before he was examined, he noticed a sudden loss of vision of the left eye. There was no preceding trauma and no associated pain, headache, nor inflammation of the eye. The right eye was normal in all respects with 20/20 vision. The left eye had vision limited to hand movements in the lower field. The globe was normal externally. The media were clear. The left fundus revealed a large, rounded, smooth detachment in the entire lower portion of the retina extending up to and beyond the macular area. The area of detachment was partly lobulated, and there was no transmission of light through the detached area on transillumination. Most of the detached area gave the impression that it was due to a hemorrhage but in the lowest portion there was some mottled pigmentation which Dr. Webster described as having the appearance of the "mottled coloring sometimes seen on a grapefruit." On the patient's admission to the Manhattan Eye, Ear, and Throat Hospital, it was found that his blood sugar content was 280 mg. percent and that the urine contained 5

percent of sugar. Under treatment for three days with insulin, the blood sugar content was brought down to 120 mg. percent, and the urine was sugar free. X-ray pictures of the chest, long bones, and spinal column were negative for metastases. When the eye was enucleated,

Fig. 1 (Laval). A cross section of the enucleated globe showing the mushroom-shaped tumor arising in the choroid and the large subretinal hemorrhage. T, tumor; B, blood; F, subretinal fluid.

there was profuse bleeding which persisted for one hour after which a gold ball was put into Tenon's capsule.

PATHOLOGY

The globe was normal in its gross appearance. On section a large hemorrhage was seen occupying approximately one third of the vitreous area. No tumor was seen until several sections were prepared for staining when a mushroom-shaped mass was seen protruding into the vitre-

* From the laboratory of the Manhattan Eye, Ear, and Throat Hospital.

Fig. 2 (Laval). There are many blood vessels in the tumor mass. V, blood vessels surrounded by tumor cells.

ous below, with blood settling toward the optic nerve and causing detachment of the retina. There was no extraocular mass.

MICROSCOPIC APPEARANCE

The anterior segment of the globe is normal. On the side opposite the tumor mass, the retina is firmly in place. The tumor mass arises in the choroid and consists of mixed round and spindle-shaped cells, closely packed, some in whorls, with much pigment and many blood spaces. At the head of the mushroom-shaped growth, some of these vessels have been perforated by the tumor cells causing a profuse hemorrhage with further detachment of the retina. The detachment extends from

Fig. 3 (Laval). The tumor cells have eroded the dilated vessel walls causing a hemorrhage. T, tumor cells invading a blood vessel.

the region of the ora serrata to the optic nerve. The choroidal vessels in the region of the tumor are quite engorged in contrast to the normal condition of the choroidal vessels on the side opposite the tumor. No emissaria are involved in the sections studied and the optic nerve is not invaded. A Wilder stain shows almost complete absence of reticular supporting fibers throughout the tumor mass.

COMMENT

The differential diagnosis between sarcoma of the choroid and subretinal hemor-

Fig. 4 (Laval). The Wilder stain (a silver stain) shows hardly any connective-tissue fibers in the tumor mass. R, reticular fibers.

rhage is often difficult. It is not unusual to see enucleated globes with a subretinal hemorrhage and no tumor, when the clinical diagnosis was choroidal tumor. The combination of both lesions, however, is quite rare and to make the correct diagnosis of tumor as responsible for the hemorrhage is extremely difficult. When a diagnosis of diabetes was established in the case herein reported, the inclination toward hemorrhage as against tumor must have been tempting, but it is to be remembered that diabetic hemorrhages are in the retina and vitreous and not subretinal.

While the sarcoma was encroaching on the vitreous chamber, the patient noticed only a slight interference with his upper field as an occasional flitting shadow. When the neoplastic process eroded the choroidal vessels with resultant profuse subretinal hemorrhage and detachment of the retina up to and beyond the macula, the effect on vision was sudden and catastrophic.

The prolonged bleeding which ensued after enucleation is explained by the use of insulin for three days prior to surgery. This was responsible for a change in blood volume. One should be very careful about the intensive use of insulin in diabetes prior to surgery of any sort.

The Wilder stain of the sections demonstrates the paucity of connective tissue supporting fibers, which is indicative of a very high level of malignancy with propensity for metastases. The tumor cells were of the mixed type, some being spindle-shaped and arranged around vessels and others rounded or epithelioid in nature. The spindle-shaped cells are less malignant in nature than the epithelioid cells. The amount of pigment scattered in the tumor was not profuse but this is of no significance as to degree of malignancy. The pigment is manufactured by the tumor cells themselves and is an indication of their reversal to their embryonic nature.

A COMBINATION RED FILTER AND OCCLUDER*

W. L. HUGHES, M.D.
Hempstead, New York

This instrument consisting of a ground-plastic red filter blackened on one end

*Made for me by Clairmont and Nichols,
517 Madison Avenue, New York.

with a handle in the middle was originally designed to simplify the technique of the parallax test.

For this test the red filter is placed over one eye, for example, the left eye with the opaque portion over the right eye. If a small, commercial green light at 20 feet is used for fixation, the patient sees only a red light. If the red portion is then moved off to the side, placing the opaque portion over the left eye and uncovering the right eye, the patient will then see only a green light. If the instrument is then moved back and forth between these two positions fairly rapidly, the patient will see alternately a red and a green light with the left and the right eyes successively. If the red light is higher than the green, a right hyperphoria is indicated. The proper neutralizing prism base down before the right eye measures the amount of hyperphoria. The horizontal balance is similarly measured. Only one hand is needed to make the complete change, leaving the other hand free to manipulate prisms.

The instrument measures 3.5 cm. by 9 cm. with a handle placed at right angles to one side. The black portion of the instrument may be used as an occluder for taking vision or performing the alternate cover test. Gross fusion may also be checked by placing the red filter over one eye, leaving the other eye uncovered, and then alternately covering and uncovering one eye with the red filter. If the patient sees a mixed red and green alternating with a plain green light, fusion is taking place. If separate red and green lights are seen when the red filter is in place over one eye, diplopia is present and it is possible to analyze the diplopia.

This instrument combines in simple form a red filter and occluder with which one can perform several tests and gain considerable information in a short time.

A STUDY OF TUBULAR AND SPIRAL CENTRAL FIELDS IN HYSTERIA*

THOMAS H. EAMES, M.D.

Belmont, Massachusetts

Concentrically contracted (or tubular) visual fields are variously regarded as symptomatic of hysteria. Ford,¹ May,² and Tassman³ have listed such fields as at least suggestive of hysteria. Yasuna⁴ presented 15 cases of hysterical amblyopia, 14 of which exhibited tubular fields, and Halpern⁵ reported 15 cases of hysterical amblyopia in which the field tracings were usually tubular. May suggested that the spiral field might be included here. In such cases, progressive contraction is noted *during* examination. Berens and Zuckerman⁶ listed spiral fields as being due to fatigue or functional causes, while Peter⁷ and Traquair⁸ were of the opinion that spiral fields occur in neurasthenia rather than in hysteria. Discussion with medical and psychologic colleagues mirrored this variation in opinion. The present study was undertaken to contribute further data to the subject.

The normal central field⁹ as tested on a tangent screen at 750 mm. with a 1-mm., white test object extends nasally 26 degrees; temporally, 33 degrees; superiorly, 26 degrees; and inferiorly, 28 degrees. Tubular fields are concentrically contracted with the same isopter distance in all meridians. Their extent is variously estimated up to about 25 degrees. The criterion used in this study was concentric contraction to 15 degrees or less from the fixation point as determined with the tangent screen under the conditions described in the opening sentence of this paragraph.

Of the 193 unselected school children

examined, 9 percent exhibited tubular central fields. The median age of these pupils was 9 years, 11 months. The median extent of their tubular fields was 9 degrees, with Q_1 , 7 degrees, and Q_3 , 10 degrees. The tubular field chartings exhibited no marked variation with changes in the test distance as normal fields tend to do. One child presented a spiral field but displayed no other evidence of hysteria or neurasthenia.

Forty-four percent of the cases with tubular central fields exhibited amblyopia sufficient to reduce visual acuity to 20/30 or less; while 11 percent showed amblyopia with visual acuity of 20/150 or less. Eighty-three percent of the tubular, central-field cases were failing in their school work in one or more subjects. Hysteria was suspected in 77 percent of the cases, and a positive diagnosis of hysteria was made in 33 percent; a provisional diagnosis, in 44 percent. Twenty-three percent of the cases exhibited no other symptom or sign of hysteria.

One of the cases presented a confused picture. This patient was failing in school, exhibited signs of hysteria, including a moderate amblyopia and tubular central fields, but he also had a concurrent illness which might have caused either or both visual impairment and central-field restriction. Unlike the others this patient's field returned to normal very slowly over a period of 14 months, during which time he received remedial teaching as well as therapy for his concurrent illness. It is impossible to determine which condition was responsible for the tubular central fields in this particular case.

Forty-four percent of the tubular central-field cases were rechecked at various intervals averaging 12 months in length. All exhibited central fields of normal size and shape when rechecked except for the single case with concurrent disease.

This study supports the contentions

* From the School of Education, Boston University, Boston, Massachusetts.

that: (1) tubular central fields occur frequently but not necessarily always in cases of hysteria; and (2) tubular central fields and amblyopia together are frequent but not invariable manifestations of that condition. It is my opinion that both these manifestations when taken together are a more reliable indication of possible hysteria than either one taken alone, since there are diseases which can influence either central fields or visual

acuity in such a way as to confuse the picture beyond reliable interpretation. Therefore, when visual acuity measurements and central-field chartings are used in examinations for hysteria, a diagnosis should not be made on the mere presence of either or both of these conditions, although the demonstration of either or both should suggest the possibility of the presence of hysteria.

A FIXATION LIGHT FOR THE CARDINAL DIRECTIONS OF GAZE*

WILLIAM COUNCILMAN OWENS, M.D.
Baltimore, Maryland

The deviations of the eyes in the six cardinal directions of gaze should always be measured in the routine study of ocular motor anomalies. To make these measurements quickly and accurately, certain important factors should be controlled and standardized. The measurements should be made with the head erect to eliminate changes in the tone of the ocular muscles induced by turning and tilting the head on the neck.¹ In addition, the measurements should be made with the eyes at

constant, standard angles of rotation from the primary position. Only by such standardization are the measurements reproducible, or comparable with measurements made on different patients or on the same patient at different times. The best method of making these measurements is by the use of the prism cover test while the patient fixates a light, for this method reveals most about the ocular muscles. In measuring the deviation by this method, the observer is constantly watching the action of the muscles as the eye moves to take up fixation. White² stated that the prism cover test "makes for much keener power of observation, and for an intimacy with the functions of the ocular muscles which cannot be acquired by any other test."

* From the Wilmer Ophthalmological Institute of the Johns Hopkins Hospital and University.

Although many instruments³ have been devised to facilitate measuring the deviation in the six cardinal directions, the use

Fig. 1 (Owens). Fixation light for the cardinal directions of gaze.

of the prism cover test with the patient fixating a light remains the method of choice. A simple fixation light for the cardinal directions of gaze has been constructed.[†] It provides a method of placing a fixation light in standard positions of gaze in the six cardinal directions. A similar method of fixation was used by Friedenwald⁴ in measuring anisophoria with a phorometer. The instrument (fig. 1) consists of a base with an upright bar, 33 cm. high, to which is attached a rotating arm, 19 cm. long. The arm rotates around the

upright bar and is provided with automatic stops that place the arm in the six cardinal meridians of gaze. Two bulbs on the rotating arm are used for fixation. One is placed at the center of rotation of the arm. It remains stationary when the arm is turned and is used for fixation in the primary position at 33 cm. The other bulb on the rotating arm is placed 15.4 cm. from the center of rotation. It moves into the six cardinal positions of gaze as the rotating arm is turned into the six standard meridians. When the patient's eyes fixate the peripheral light, their constant angle of rotation from the primary position of gaze is 25 degrees in each of the six cardinal directions.

The instrument is used on a table with an adjustable head and chin rest (fig. 2). The central light is placed directly in front of the patient at a distance of 33 cm. First the peripheral light is turned off, and the patient fixates the central light while the deviation of the eyes in the primary position for near is measured by the prism and cover test. Next the central light is turned off, the peripheral light illuminated, and the arm placed successively in each of the six cardinal meridians. While the patient fixates the peripheral light, measurements of the horizontal and vertical deviations are made by the

Fig. 2 (Owens). Fixation light for the cardinal directions of gaze being used with the prism cover test.

[†] Built by Mr. Albert Goebel in the machine shop of the Wilmer Ophthalmological Institute.

prism and cover test in each of the six cardinal directions of gaze. The light is easily shifted from one position of gaze to the next by simply rotating the arm until it comes to the next automatic stop.

This instrument is extremely useful for it standardizes the position of gaze in the six cardinal directions. With it, measurements can be made more quickly and accurately, for the operator's hands are free, and there is adequate, unencumbered working space. The action of the

eyes can be easily visualized by using the prism cover test, and the corneal reflex of the uncovered eye can be watched constantly. The instrument is simple and can be used readily with both adults and children. It is particularly helpful with children, for the head is held in a constant position and the child enjoys watching the fixation light swing into the cardinal positions of gaze as the arm is rotated into the six meridians.

PATHOGENESIS OF FUNDUS CHANGES IN SKULL INJURIES*

Z. KAMINSKAYA-PAVLOVA, M.D.

Moscow

Skull injuries, as is known, are frequently associated with fundus changes. The pathogenesis of these changes is not always clear, especially if the fundus changes develop some time subsequent to the trauma, and there are no signs in the central nervous system (abscess, meningitis) to account for the fundus changes. Such circumstances always complicate the management of the case. Usually in such cases therapy is symptomatic, not

etiologic which makes it less effective.

We would like in this brief presentation to call attention to one factor which sometimes plays a dominant role in the development of various posttraumatic changes. This factor may be the background against which the posttraumatic picture develops.

On one hand, trauma may serve as the stimulus which awakens within the organism a latent pathologic process; on the other hand it weakens the organism and lowers its resistance so that a hidden pathologic process becomes virulent. For instance, numerous cases of luetic parenchymatous keratitis, which set in following an injury, have been reported in the literature. It is also known that in cases of tuberculous allergy, the traumatic

* From the third Moscow Medical Institute.

site fixes the bacterial metastasis. This was demonstrated through numerous experiments for various organs, including the eye (Rappoport, Kaminski).

Clinical observation also demonstrates that trauma not infrequently leads to the development of tuberculosis in the traumatized organ. For instance, cases of a perforating ocular injury followed by a tubercular process, and diagnosed histopathologically, have been reported.

All this testifies to the important role of the background against which the traumatic process develops. The importance of the premorbid state is so great that not to recognize its importance in the analysis of the pathogenetic factors would be a grave error.

CASE REPORTS

Several cases under our care serve as vivid illustrations of this situation, and we therefore report them briefly.

Case 1. A man, 40 years of age, was seen because of rapidly diminishing vision. This condition developed after a comparatively mild bump of the forehead against an iron rod. The patient did not lose consciousness, but was dizzy for some time. Immediately after the injury, he noticed rapid diminution of vision. One month later at the time of examination, vision was: 0.03 and 0.04. The fundus revealed a descending atrophy of the optic nerve. A careful neuropathologic examination made one suspect lues. An analysis of the cerebrospinal fluid, as well as the subsequent clinical course, confirmed the diagnosis.

In this case, it would seem that the injury served as the stimulus for the development of a process, which might have developed anyway. Trauma, however, hastened development of the disease and made the prognosis unfavorable. The patient rapidly became blind.

Case 2. Even more interesting is this case of moderately pronounced oxycephaly. The fact that the man was a sniper justifies the assumption that his vision was good. During a battle he suffered a contusion. Following the injury he began to suffer persistent pain in the head, and vision began to fail. Examination revealed a secondary optic atrophy. Visual acuity was 0.01 in each eye. There is the possibility that the optic atrophy preceded the injury, because it is frequent in oxycephaly. However, a record of good visual acuity prior to the injury indicates that, even if the patient did have an optic atrophy, it did not affect his vision. The injury, having fallen on fertile soil, resulted in the rapid development of a process which ended in almost total blindness.

For purposes of observation the patient was placed in the neurologic clinic, where it was found that he had arachnoiditis with raised intracranial pressure. In the opinion of the neuropathologist, the raised intracranial pressure was undoubtedly related to the oxycephaly. The literature contains the description of a similar case (Birm) in which, after an injury, a man with oxycephaly suffered rapid deterioration of vision. He had an optic atrophy.

Case 3. This case is unique. A woman with Raynaud's disease suffered a skull injury in an automobile wreck. Following the injury, she developed a cerebral form of Raynaud's disease with attacks of acute cerebral anemia. During these attacks, we could observe sharply pronounced arterial spasms in her fundus. Thus, the trauma served to transfer the site of the disease from the extremities to the central nervous system.

Case 4. This case deals with a skull injury in a hypertensive patient. A woman, 45-years-old, with vascular hypertension

fell and injured her head. There was a brief loss of consciousness, with dizziness and headache.

At the first examination it was found that she had peripapillary edema. Her general condition became aggravated; she began to have attacks of unconsciousness and was hospitalized. Her blood pressure was high (170/105 mm. Hg.) After two months of hospitalization, she was discharged in a satisfactory condition. The attacks recurred and soon she developed markedly choked discs. She was again hospitalized. Repeated lumbar punctures led to considerable improvement; the choked discs disappeared, leaving slight edema. Soon after discharge from the hospital, symptoms again recurred, and vision, which until then was normal began to fail.

The neuropathologist explained the case in the following manner: "An insignificant trauma gave rise to serious complications and an unfavorable course, only because the patient had hypertension. Hypertension in this case formed the background which determined the character of the clinical course of the disease, giving it a grave form, not associated with light trauma."

Case 5. A man, aged 30 years, developed a descending optic atrophy with vision reduced to 0.3 following a skull injury during a bombardment. The trauma was light; there was no loss of consciousness; the visual loss was gradual, beginning with a central scotoma which gradually disappeared. The history revealed that this was the third skull injury sustained by this patient. The first was during infancy when he fell from the roof of a barn. The last two injuries were sustained within 1½ years during the war. The last injury resulted in more severe complications than the other two. In addition to optic atrophy, it caused

neurologic symptoms such as headache, dizziness, paresthesia, and so forth. The case was regarded as a traumatic arachnoiditis caused by repeated injuries.

DISCUSSION

These five cases, with the common etiology of injury to the skull and different backgrounds against which posttraumatic symptoms developed, demonstrate the importance of a careful study of injuries.

Among posttraumatic changes, optic atrophy is a frequently encountered phenomenon, and yet, it is frequently difficult to understand why an optic atrophy should develop following an injury, particularly if it was slight. The pathogenesis of optic atrophy is clear in cases in which there is bone injury, and in those in which a fracture of the optic canal is suspected. Sometimes the cause of the optic atrophy is a hemorrhage into the meninges of the optic nerve. Complications such as meningo-encephalitis or abscess of the brain may also lead to optic atrophy.

Along with these more familiar cases, we encounter cases which we do not understand. In such cases it is important to get a detailed history and make a careful examination. Congenital anomalies, previous illness or trauma, the presence of latent pathologic processes (lues, malaria, tuberculosis, hypertension, septic foci, and so forth) may serve as fertile soil for the development of posttraumatic complications. Not only may these conditions initiate development of the disease, but they may also aggravate its clinical course. Demonstration of these factors facilitates understanding of the processes involved and helps in the application of rational therapy.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

May 6, 1946

DR. MAURICE L. WIESELTHIER, *presiding*

DANGER OF PENICILLIN IN ACTIVE UVEITIS

DR. ELTON YASUNA said that, after intramuscular injection, only low levels of penicillin are found in the aqueous, even with massive doses. The most satisfactory aqueous concentration is obtained by topical administration, using penicillin-saturated cotton packs in the lower fornix. In severe infections, injections, both subconjunctival and directly into the aqueous, have been employed, but these cause irritation.

Penicillin has been found to be effective in the treatment of the purulent infections of the external eye. However, in uveitis most reports show that penicillin is not effective.

Two case histories were presented. Both patients had uveitis, possibly Neisserian in etiology. In each instance, the uveitis was subsiding under the usual therapy when intramuscular penicillin was begun for the chronic urethritis. The uveitis became worse, and the penicillin treatments were stopped, following which the eyes rapidly became quiet.

A possible explanation for this exacerbation was proposed. The inflammatory process in uveitis is probably not a result of direct bacterial invasion, but rather due to tissue sensitivity from bacterial end products. Also, it has been shown that the action of penicillin is bactericidal. Therefore, penicillin administered systemically

causes destruction of bacteria in the focus of infection. This liberates more bacterial end products into the blood stream, which further aggravates the active uveitis.

It was suggested that penicillin should not be used in active uveitis because its therapeutic value is doubtful, and because it may actually be dangerous.

PLASTIC SURGERY OF THE EYELIDS

DR. WENDELL L. HUGHES places emphasis on the division of the lid into two layers, surgically, cosmetically, and functionally. When less than one fourth of the upper lid is missing, the remaining portion of the lid can frequently be pulled together and joined with a tongue and groove joint, supported by a flap of skin just back of the lid margin. When one fourth to one half of the lid is missing at either the nasal or temporal sides, the remaining portion of the lid can usually be divided into two layers and one layer slid across into the defect. It is usually better to slide the tarsoconjunctival layer across into the defect and then put a skin graft over this area. The tarsoconjunctiva is left attached to the levator.

When the upper lid is entirely missing, a major procedure with several steps is necessary. First, the conjunctiva must be brought across the cornea to protect it. The conjunctival surface is kept in contact with the corneal surface. Skin is then slid from nearby areas to give a double layer over the eye with which to start. Additional skin must usually be provided. Tarsoconjunctiva as a free graft can be taken from the opposite upper lid, if it is normal. Skin is taken from the opposite upper lid, and lashes for the upper lid are taken from the brow on the

same side. An almost complete blepharorrhaphy is maintained for the duration of the several stages in the reconstruction of the upper lid. It usually takes more than a year to complete the reconstruction. If the levator has been severed, it may need to be reattached to the newly constructed upper lid. A tarsorrhaphy or blepharorrhaphy is almost always necessary in reconstructing any major portion of the upper lid.

USE OF FREE-SKIN GRAFTS

DR. J. EASTMAN SHEEHAN illustrated his new method of dealing with free-skin grafts, explaining that, although in the beginning there was a 50 percent loss, now there is practically none. The advance was illustrated by a case in which, under his method, sutures are not necessary. Circulation is reestablished so rapidly that overlapping edges, if allowed, bleed when cut on the second day. Definite recovery is achieved on the 14th day, and in two months the graft cannot be distinguished from its surroundings.

What is new about the method is the addition of certain blood elements. At the time of operation the patient himself supplies blood drawn by an aspiration needle. It runs to 10 cc. capacity. To maintain fluidity, 1 mg. of heparin and 1 cc. of Tyrode's solution are added. This overcomes the tendency of a graft to shrink. The graft, made fast to gauze, is transferred to the wound area, which it precisely fills. A margin of the gauze holds it in place.

The graft is held firmly in place by an extract from the blood. After the blood has been centrifuged for 20 minutes, there is clear plasma at the top, a thin film of white cells, and the red corpuscles. These last do not enter, but the other two do. The recipient area is painted with the plasma. The under side of the graft is also painted, a different color.

With the rubberized fabric held up by an assistant, the operator guides the graft to its place. Fixation is complete. The particles from the blood hold the graft in place.

The process of recovery is interesting to watch. The graft takes on a purplish tinge after five hours, gives signs of life after 10 hours, is a full purple on the third day, a definite pink on the 14th day.

Discussion. Dr. Raymond E. Meek described the operation he has devised for the correction of entropion. He stated that the circular fibers of the orbicularis oculi have two directions and functions. The circular fibers which run around the eye elevate the lower eyelid by contracting and flattening the arc, while at the margin of the lower lid they curve in the horizontal plane pulling and holding the lid against eyeball. He changes the direction of these fibers, which cause the spastic entropion, and corrects the condition by making a horizontal incision the full length of the lid and 3 mm. from the margin. The skin is undermined and two tongues of the exposed orbicularis are dissected so that they remain attached at the center of the eyelid. Incisions from below the center are made downward and laterally to the orbital margin and with catgut, tongues of orbicularis are sutured to the periosteum without any tension. The skin is closed with interrupted silk sutures.

Dr. Clarence R. Straatsma said that plasma glue was used for a time at the Brooklyn Naval Hospital. While the results were favorable, its use was ultimately discontinued because the frequent change in personnel made it necessary to train new help repeatedly. It was found that the procedure was more uniform and stable when more thrombin was used.

Dr. Sidney A. Fox said that he was happy to hear Dr. Hughes say that it is rare to achieve results equal to the normal

condition. He agreed with Dr. Hughes's use of tarsal cartilage to replace tarsal cartilage and said that he always tries to replace tissue with the same tissue although there are usually several methods of correcting any particular condition.

Slides illustrating several cases were shown. In several of these preserved cartilage was buried under the skin and after a few weeks the skin and the now adherent cartilage swung into position on a pedicle to the skin-tarsal layer of the new eyelid.

DR. GEORGE P. LANDEGGER, *presiding*

AN IMPROVED PROCEDURE IN PROSTHESIS PLASTIC SURGERY

DR. S. V. ABRAHAM presented a preliminary report on a new technique for evisceration with sparing of the cornea and scleral implantation. He pointed out that the only similar technique for evisceration with saving of the cornea was brought out by Burch in 1939.

In Burch's technique, the conjunctiva is dissected free of the limbus for four fifths of the limbus. The sclera is exposed for an area about 5 to 6 mm. from the limbus. The sclera is then incised about 5 to 6 mm. from the limbus, and the incision enlarged, running more or less parallel to the limbus and through four fifths of the circumference of the globe. The evisceration is then completed, including scraping of the posterior surface of the cornea. An implant is inserted and

the scleral wound is closed. The conjunctiva is sewed to the limbus area. Dr. Abraham pointed out that Burch's technique leaves the scleral wound anterior and in close contact to the conjunctival wound. The opening, he said, encircles the globe for four fifths of its circumference.

Dr. Abraham described his technique as follows: A conjunctival incision running parallel to the limbus is made temporally about 7 to 8 mm. from the limbus. The incision runs approximately from the superior rectus downward for about $\frac{3}{4}$ to 1 inch. The sclera, he stated, is exposed anterior and posterior to the conjunctival incision, the conjunctiva being retracted. The external rectus muscle is identified. The sclera is incised parallel to the upper rim of the external rectus muscle and 2 to 3 mm. above the same. The incision is carried backward and forward as far as desired to permit not only easy access to the ocular contents, but also the implantation of a large ball. The anterior end of the scleral incision should be at least 2 mm. from the limbus. He went on to say that after removing the ocular contents (and scraping the posterior corneal surface if desired), the implant is placed within the sclera, using as large an implant as possible (18 to 22 mm.), and the scleral wound is closed with interrupted mattress sutures. The conjunctiva may be closed with a running suture.

This technique permits scleral implants of larger size, with minimum danger of extrusion. The deep incision contacts the superficial incision in only one point. Dr. Abraham said that the incision runs in the direction of the major pressure from within the globe and the orbit, so minimizing the possibility of extrusion. He pointed out that the final result is a larger stump, with greater retention of the normal conjunctival tissue and folds,

thus making for better cosmetic results.

He also emphasized that better results occur with the preservation of a maximum stump, the maximum retention of a normal conjunctival sac, and the use of a minimum sized artificial eye. Saving of the cornea is essential for the retention of a maximum conjunctival sac.

Discussion. Dr. G. Zugsmith reviewed his observations of more than 1,000 cases in the army. These cases, he said, had had enucleation without implantation, enucleation with implantation, evisceration without scleral implant, and evisceration with scleral implant. Some of his cases had been operated as long as 25 years before observation, and some cases were done only a short time before observation. Dr. Zugsmith observed that surgery had similar pathologic results in all the cases; that is, there was a shrinkage of the orbital tissue with a contraction or atrophy of the conjunctiva, and a tendency of the orbital contents to sink to the floor of the orbit. Dr. Zugsmith found that these pathologic changes were least in cases of evisceration with scleral implant, and most with enucleation without implantation. He found that the cosmetic results were, therefore, best with evisceration and scleral implant. He reported that his experiences did not include scleral implant with saving of the cornea.

BILATERAL GLIOMA OF RETINA

DR. MARIO ESTEBAN presented a case of bilateral glioma of the retina. A boy aged two years, whose right eye has already been removed for glioma of the retina, now shows in his left eye the ex-

istence of a tumor of like malignancy. You are all familiar with the prognosis as to life of such a condition. The case is as interesting from the clinical standpoint as it is touching from the human standpoint because of the dilemma as to whether to enucleate the second eye.

What else can be considered except enucleation? For the past few years radiotherapy has been tried and conscientiously followed. In the beginning, the tumor showed evident regression from the effect of the radiation, but now it seems to be moving again toward the papilla. Should we persist? Should we continue with such treatment? Or should we decide on an operation?

The results of the roentgen therapy in glioma of the retina are not conclusive. There are those who claim that X-ray treatments can cure a glioma and preserve the eye. Others maintain that every glioma will end fatally as regards the eye and life itself if enucleation is not done in time. They advise treatment with X rays—not to avoid an operation, but as a complement to it—before an operation in order to prevent metastasis and afterward to prevent recurrences, or both before and after for the double purpose indicated.

Radiotherapy is a valuable device which should be considered in tumors of this kind. We can and we should try it first in all such cases, but we cannot and should not trust in it exclusively. We have to observe the effects, watch developments, and be prepared to enucleate if necessary before extensions and metastasis develop. We must keep in mind that blindness cannot be avoided by not operating because the glioma itself destroys the eye. The operation at least will save the child's life.

In case of such a tumor in both eyes, which occurs unfortunately all too frequently, we ought to at first apply radio-

therapy. But if this fails in one eye or the other we must enucleate both eyes. It is our duty to do so, cruel and painful as the process may seem. There are no scientific, ethical, or social reasons to allow the child to die. On the other hand, blindness is not a renunciation of life; it is perhaps a more subjective and a more intense life, and the blind are not more unfortunate or less useful to society than the majority of those who see.

Glioma of the retina not only constitutes a very important clinical problem, but also a social problem. It has been proved that some adults, who were afflicted in infancy with glioma of the retina and whose eyes as a result were enucleated, bear children who also suffer from the same affliction, which shows that glioma is hereditary. Enucleation and the subsequent application of X rays are definitely indicated, and there is nothing else to do.

Discussion. Dr. Garcia Mansilla said that the case of double glioma of the retina which Dr. Mario Esteban presented to us is very interesting from a medical and moral aspect. From the first aspect, I believe that Dr. Esteban would act very well in enucleating the eye and then applying radiotherapy to the orbit in order to avoid the recurrence of the neoplasm. I believe that having the glioma already manifest in the other retina it is likewise necessary to do another enucleation, preceded and followed by radiation. In this way, it is possible to avoid the recurrence and metastasis of the neoplasm in distant organs. From the moral aspect, it is truly painful to enucleate the single eye which the boy has, although vision is rather poor. However, considering that whatever vision he has will shortly be lost and that the operation is the only way of saving life, I believe it is proper to convince the father of the patient that he should authorize the operation, because he cer-

tainly would prefer that his child should live even though blind. Moreover, we must also remember that when sight is lost early in life the individual adapts himself to his new condition easily and such blind individuals are as happy as many seeing ones. Bearing out this point, I know a man, aged 56 years, who as a child suffered double choriocyclitis, as a result of which he became completely blind, did not even see the slightest ray of light. I took care of him some 50 years ago. He now lives happy and contented. He is a masseur in an important establishment in Madrid and has many high-class, private patients and earns a good livelihood.

Dr. Carreras said that he entirely agreed with Dr. Mario Esteban in the manner in which he is handling this case of bilateral glioma. The enucleation of the second eye is important in order to save or try to save the life of the child. This is the first duty of the doctor even though it shows the failure of the ophthalmologist. The sacrifice of the other eye is most difficult for the parents. The child at this young age can receive an education which will enable him not only to be happy but also to be useful to his country. There have been many blind men who have become outstanding.

Dr. Galindez Rivero congratulated Dr. Mario Esteban for the presentation of his interesting case and for the conscientious examination which he had made. Truly the problem which presents itself to a child with glioma is very serious. Moreover the loss of sight becomes secondary to the peril of losing the child's life if appropriate measures are not rapidly instituted.

First of all, X-ray treatments should be tried, as Dr. Mario Esteban has well said, and the child should be watched so as to proceed immediately to enucleation, if necessary. Radiotherapy treatment ap-

pears to be always of some benefit. When the diagnosis is made early, good results can be obtained (Axenfeld). When the condition is already far advanced, it will prevent metastasis and provide better results after enucleation. The parents should be advised that glioma is congenital and that periodic examination of the eyes of the other children must be made in order to apply very early radiotherapy, if necessary. If the radiotherapy does not show any favorable results, enucleation of one eye or of both must be resorted to. If, as in this case, glioma is bilateral it certainly is terrible to tell the parents that enucleation is obligatory, but it is necessary to save the child's life. I am in complete agreement with Dr. Mario Esteban that there are no scientific, ethical, or social reasons for allowing the child to die. He may grow up to be a useful citizen and lead a happy and contented life.

ECTASIAS OF LACRIMAL SAC

DR. MARIN AMAT AND DR. MARIN ENCISO discussed the treatment of ectasias of the lacrimal sac by resection of the anterior wall, with presentation of patients. The immediate results are excellent. The operative technique is as follows:

1. Local anesthesia with 2-percent novocain in the same way as for dacryocystorhinostomy.

2. Curvilinear incision of the skin and superficial aponeurosis, identical with that which is in practice for dacryocystorhinostomy.

3. Separating with a blunt instrument the muscular fibers which cover the ectasia so as to expose the tendon of the orbicularis muscle and the anterior face of the lacrimal sac, so that it is freed from the surrounding tissues.

4. Sparing the tendon of the orbicularis, a portion of the anterior face of the sac is resected as much as is considered necessary by means of two slightly curvi-

linear anteroposterior incisions (the patient being in the horizontal position), by means of which the cavity of the sac is opened and its contents evacuated.

5. Introducing through the cavity into the nasal duct, whether this is open or not, a thick lacrimal, olive-tipped probe (no. 5 or 6) in order to enlarge the duct, if it is open; or to perforate it, if it is obstructed.

6. Suturing the lips over the resected part of the anterior wall of the sac with silk. The sutures should be somewhat thick and resistant in order that they can be easily removed. We use a continuous suture leaving the ends a little long in order to pass the upper thread under the lower border of the tendon of the orbicularis and take it out through the skin about 1 cm. from the wound, and we tie it to a rosary bead. We then tighten the silk suture and take it also through the skin about 1 cm. from the wound and tie it in the same way to another rosary bead. In this way, drawing on the silk sutures raises the anterior wall of the sac.

7. Suturing the skin by interrupted sutures.

8. If there is no communication between the inferior lacrimal canaliculus and the lacrimal sac, we reestablish it.

9. The lacrimal sac is washed with sterile water in order to clean out the small amount of blood that might stay there and to make sure that the passages are all clear. Generally we do this step as soon as we have made the deep suture and with the cutaneous wound still open so that we are in a position to introduce modifications which may be necessary.

10. Place a sterile piece of gauze on the operated region, and fasten it with a strip of adhesive.

Discussion. Dr. Carreras said that he wished to congratulate the authors of this interesting communication on this procedure if it gives such good results as ap-

pears from the small number of cases treated by them. This will solve a problem for which the only satisfactory solution so far has been dacryocystorhinostomy, which is a much more formidable procedure, and the results of which are less natural. However, we have to wait some time before accepting the new method, because, more than for the immediate results, we must watch for the final and permanent results. It is well known that probings will solve for a time the problem of epiphora, but that later the condition returns slowly and progressively, and the passages which were forcibly opened by probing close again. I, myself, had occasion to attend patients in the beginning of my professional career in Gerona, who had been treated by probings by my late father and who were dismissed as cured because the epiphora had ceased; yet that did not prevent the epiphora from recurring after a variable time. It is, therefore, desirable that the successes obtained by Drs. Marin Amat and Marin Enciso be confirmed by a large experience to which I expect to contribute with the cases which I have.

Dr. Galindez Rivero congratulated Drs. Marin Amat and Marin Enciso on their interesting presentation. He said the method is original, is simple, traumatizes little, and, in the cases for which it is indicated, provides ideal treatment for this affection of the lacrimal passages. That is, it cures the ectasia of the lacrimal sac and restores the normal course of the tears, eliminating epiphora—a condition which is a nightmare to both patient and doctor—and does it in a manner which is simple, gentle, and accessible to everybody.

I promise to apply the procedure of Drs. Marin Amat and Marin Enciso in suitable cases and report on the results obtained.

DR. BURTON CHANCE, *chairman*

A CASE OF STEVENS-JOHNSON DISEASE

DR. BRUCE A. GROVE and DR. EDMUND MEISENHOLDER (by invitation) said that Stevens-Johnson disease is generally considered to be a manifestation of erythema exudativum multiforme first described as a clinical entity by Von Hebra in 1866. The lesions occur in the conjunctiva as well as on the mucous membranes of the mouth, nose, pharynx, larynx, trachea, bronchus, and genitalia. Conjunctivitis may be the first symptom of the general disease, and according to Duke-Elder may take three forms: namely, a relatively mild catarrhal, a purulent, or a severe pseudomembranous affection.

The first recorded case of ocular involvement was described by Fuchs in 1876 as "herpes iris conjunctivae." From cultures reported, staphylococcus aureus is more commonly found than any other organism. The disease is of sudden onset with high fever and marked constitutional symptoms which gradually subside. The patient usually recovers in about 18 to 21 days. Although the prostration is severe, the mortality rate is low, only four deaths having been reported.

A review of the literature illustrates the confusion existing among writers as to proper cataloging of the disease.

Case Report. A white man, aged 30 years, first complained of light hurting his eyes. Examination revealed mild injection of the palpebral and bulbar conjunctiva. Within 24 hours he was violently ill, and his temperature rose to 103.2° F. There was a skin rash consisting of macules, papules, and intracutaneous

vesicles. Involvement of all the mucous membranes and mucocutaneous junctions and severe pseudomembranous conjunctivitis were noted.

The patient was discharged on the 21st day following onset of the disease with no loss of visual acuity, slight symblepharon, marked scarring of the palpebral conjunctiva, and occlusion of all the puncta. Drug and serum reaction was ruled out as causative agents. Acute vitamin deficiency was suggested as a causative factor. The writers concluded that Stevens-Johnson disease is a severe form of erythema exudativum multiforme with involvement of the conjunctiva whether it be catarrhal, purulent, or pseudomembranous.

Discussion. Dr. John F. Wilson said that Stevens-Johnson disease is considered by many authorities to be erythema multiforme, and the slides which Dr. Grove showed very well demonstrate the extensiveness of involvement which may occur in this disease. Not only bullae were present, but there were in addition various other lesions on the skin; namely, macules, papules, and pustules. The disease, erythema multiforme, produces multiforme lesions, which involve any of the dermal areas or the mucous membranes. It is thought to be due to a virus, although the virus has never been demonstrated. It is possible in Dr. Grove's case that a dietary deficiency lowered the patient's resistance so that such a virus gained a foothold in the patient.

It is important to differentiate the changes in the eyes in this case from those occurring in pemphigus vulgaris. There are three outstanding characteristics seen in this patient which will differentiate his disease from the changes seen in pemphigus vulgaris. These are not directly relative to the ocular structures. First, as Dr. Grove mentioned, pemphigus is usually found in older patients. This patient is now 30 years of age. He was about 28-

years old at the time of the attack. Second, the onset of the disease, unlike pemphigus, was sudden and severe. Within 24 hours, this patient's disease had almost reached its peak, and from that time on it gradually improved. The third factor is that the course of the disease lasted a total of 19 days. Pemphigus, however, is characterized by a longer term with exacerbations and remissions, and ultimately a fatal outcome.

There is one special type of pemphigus that could most likely be confused with this type of disease, and that is pemphigus of the mucous membranes, or localized pemphigus. This type is characterized by outbreaks of bullae in various areas of the skin, but occurring only in involvements of small areas at a time. There are then relapses with similar small areas showing the involvement, but ultimately the reaction becomes generalized. All of the skin and mucous membranes are affected, and the disease terminates fatally. It has a chronic course.

As Dr. Grove mentioned, Duke-Elder in his conclusions includes in the eye involvement of erythema multiforme, three types: the catarrhal, purulent, and pseudomembranous stages. He believes, and I think most of us agree with him, that these are changes in degree rather than in type. In other words, the pseudomembranous type shows the most severe changes in erythema multiforme involving the ocular structures. That point is aptly demonstrated by the penile lesion in this case. It bears a very close relationship with the ocular lesion, and shows a similar bandlike scar holding down the prepuce to the glans.

Dr. W. Zentmayer said that he did not wish to discuss the paper itself, but that he wanted to speak about the title of the paper. This was no criticism of the authors, because they have a precedent for the titles they use. When a general disease commonly has eye complications, it would

seem a questionable procedure to make an entity out of cases that happen to have eye complications that are a little more severe. By the same token, one might just as well speak of the Wheeler syndrome, because Wheeler's case was much more severe, developing panophthalmitis with loss of the eye. It would seem that it is pretty difficult to make out an entity for this group of cases of erythema exudativum multiforme. Furthermore, there is objection to using authors' names to designate a syndrome. The title gives no indication as to the subject matter of the paper. If one wants to search the literature for a certain condition, he may overlook cases that are published as an author-named syndrome.

Dr. Burton Chance said that he agreed with Dr. Zentmayer. It is quite difficult to know exactly to what the names of those two gentlemen might refer. The title would have been understood if it had denoted a special type of multiforme erythema.

ACQUIRED OPHTHALMIC ALLERGY

MAJOR WILLIAM F. BONNER (MC), A.U.S. (by invitation) discussed this subject. He said:

1. Acquired allergy may be single or multiple.

2. The most common offender is atropine, which may cause dermatitis and intraocular hemorrhage.

3. Quinine amblyopia may be acquired, and the one case reported was helped by 50,000 units of vitamin A, three times daily.

4. Hemorrhagic allergy was improved by padutin.

KERATITIS ASSOCIATED WITH LYMPHOGRANULOMA VENEREUM

DR. HAROLD G. SCHEIE and DR. ALAN S. CRANDALL (by invitation) discussed four patients who had identical corneal lesions of a distinctive type associated

with lymphogranuloma venereum. Evidence supporting the designation of the lymphogranuloma-venereum virus as the etiologic agent was considerable. (1) The corneal lesion was so characteristic as to suggest the diagnosis of lymphogranuloma venereum in all of these patients. (2) Diagnosis of the systemic disease was further established by additional clinical or laboratory evidence or both. (All had positive Frei tests. Two had scars of healed bubos and one had active inguinal involvement. The fourth patient showed no other clinical evidence of lymphogranuloma venereum, but did exhibit a strongly positive complement-fixation test, and a biopsy of the corneal lesion showed histologic changes compatible with the disease.) (3) The corneal lesion was always found associated with a positive Frei test and never with any disease other than lymphogranuloma venereum. (4) The lesions were identical with those occurring in a patient having lymphogranuloma venereum reported by Meyer and Reber in 1940.

Discussion. Dr. Henle said that they had had the opportunity to study in the laboratory one of the cases Dr. Scheie had just presented. The results obtained, thus far, served well to demonstrate the possibilities as well as the limitations of a diagnostic laboratory for virus infections. There are three general approaches to the laboratory diagnosis of a virus disease:

1. The isolation and identification of the causative agent.

2. The determination of the serologic response in the patient.

3. The demonstration of characteristic pathologic lesions.

All three approaches were used in this case. In discussing it, he would like to begin with the third approach, the demonstration of characteristic lesions. Part of the material obtained by biopsy from the cornea was sectioned and stained with Giemsa's stain. On examination many

epithelial cells were found and, in some regions of the section, practically all of them contained cytoplasmic inclusions. These consisted of aggregations of small, round bodies staining dark purple. In many places, individual or small groups of these particles were found. They had a diameter of between 200 and 300 μ , and probably represented the elementary bodies of the virus involved in this case. In lymphogranuloma venereum, such inclusions were first fully described by Miyagawa as granulo-corpuscles.

The serologic studies were likewise in accord with what one would expect to find. The complement fixation test with lygranum antigen (Squibb) was high, giving a serum antibody titer of 1:256. The antigen used was the same as that employed for the Frei test, which also was positive as Dr. Scheie pointed out.

As for the isolation of the causative agent, studies were not completed, as yet. The number of elementary bodies visible in the section would imply that the virus should be isolated with ease. On the other hand, the high antibody level in the patient's serum may cause considerable difficulties. In order to release the virus from the cells, the tissues have to be emulsified by grinding in a mortar with an abrasive, and it is impossible to avoid the contact of antibody with the virus; thus, some virus may be neutralized before the injection of the emulsion into experimental animals.

The first attempt at isolation of the virus was made by intracerebral injection of white mice. They developed no lesions. On the 12th day they were killed and their brains, after emulsification, passed to new mice. Again no lesions developed, and this line was discontinued.

A second attempt was made in the chick embryo. In this case the remaining material from the biopsy, which had been kept at -10°C ., was injected into the yolk sac of eight-day-old chick embryos.

They survived eight days of further incubation when the yolk sacs were harvested. A 20-percent suspension was passed to new eggs and also to white mice by the intracerebral route. These mice showed some signs of cerebral lesions on the fourth and fifth day. They lost weight, and on suspension by their tails they exhibited tremor, and on release had difficulties in regaining equilibrium. Passage of the brains from these mice to other mice produced severer lesions and death. As can be seen, there is a chance that the agent has been isolated from the biopsy material. If so, it has to be identified by neutralization of the agent with known specific immune sera as well as with the patient's serum. The possibility of having activated a latent virus in the mice has to be excluded.

What do the various data imply? The virus of lymphogranuloma venereum belongs to a group of agents which have been classed together on account of various properties they have in common. In this group of agents we find, besides the lymphogranuloma-venereum virus, the agents of psittacosis, ornithosis, meningo-pneumonitis, trachoma, inclusion blenor-rhea, mouse pneumonitis, and others. They all form similar cytoplasmic inclusions and exhibit serologic cross-reactivities. Neutralization of the toxic activity of these agents, described by Rake and Jones, constitutes the most specific test and serves best to differentiate between the various viruses of this group.

From the data presented, there is little doubt that the agent involved in the presented case belongs to this group of viruses, but we cannot say as yet with definite assurance that it is a strain of lymphogranuloma-venereum virus. Although all results seem to be in accord with this diagnosis, a differentiation between the various inclusions cannot be made with sufficient accuracy. The high complement-fixation titer with lygranum

antigen appears quite significant, but may not be out of the range of cross-reactions observed with some of the other viruses of this group of agents. Fairly strong cross-reactions with lygranum antigen have been reported, for instance, with serum from cases of psittacosis and of pneumonitis. The Frei test, too, has been found weakly positive in some cases of psittacosis, meningo-pneumonitis and atypical pneumonia. The final diagnosis hinges on the isolation and characterization of the causative agent.

Dr. I. S. Tassman said that he would like to ask Dr. Scheie whether he observed the characteristic conjunctival lesion in any of these cases of lymphogranuloma venereum. He believes that the typical lesion occurs on the conjunctiva in this disease, and it seems unusual for keratitis to occur as a manifestation of this condition. Can Dr. Scheie tell just what it was that made him recognize this form of keratitis as typical or characteristic of lymphogranuloma venereum?

Dr. Tassman had recently observed two cases similar to the ones described. These cases cleared up under treatment with sulfa drugs, and a third case improved with penicillin treatment. There was no clinical evidence of lymphogranuloma venereum present in any, although laboratory tests were not made.

As was pointed out by Dr. Henle, there are several other conditions in which the Frei test may be positive. It does seem that Dr. Scheie's case in which the laboratory findings were positive can be accepted as a real case of lymphogranuloma venereum. In the others, however, the diagnosis would be a presumptive one.

Dr. Warren S. Reese asked whether this lesion had any resemblance to the so-called salmon patch seen in interstitial keratitis.

Dr. George F. J. Kelly asked: Does sulphonamide therapy alter the findings of subsequent Frei tests? The recurrences

that were reported in two cases were thought to be due to inadequate treatment. Is there any known standard of treatment to prevent recurrences?

Dr. Alan S. Crandall said that it might be interesting to mention how the presumptive diagnosis was made in the last case. The patient had been seen several times, and lymphogranuloma venereum was not suspected. While the case was being studied, it was compared with a picture which Dr. Scheie had brought back from India. This picture showed keratitis in a patient diagnosed as having lymphogranuloma venereum. The similarity of the lesions was so striking that an immediate study of the patient was made with this disease in mind.

From the study of these few cases, Dr. Crandall believes that the lesion is characteristic of lymphogranuloma venereum. However, by the time the lesion becomes typical, there is permanent corneal damage. There will be some scarring and vascularization. It would be well if the index of suspicion were high enough so that the patient could be treated adequately before permanent damage occurs. It is important to reiterate the need for continuous treatment for a period of at least three weeks. The two patients who did not do well did not keep up adequate therapy.

Dr. Harold G. Scheie (closing) said that he believed there was little question that the lesion discussed was primarily a keratitis rather than a conjunctivitis. In the one case seen early, the onset was associated with symptoms of conjunctivitis, but promptly the corneal lesion appeared. All of the patients herein discussed, as well as the one of Meyer and Reber, seemed to show only secondary injection of the conjunctiva. There were no granulating lesions on the conjunctiva, and adenopathy was not observed.

The appearance of the corneal lesion seems characteristic and specific for the

disease. Most important is the slitlamp examination. The involvement of the cornea is through its entire depth. The lesion first appears within the upper limbus. Two of these patients subsequently developed a similar corneal infiltrate within the lower limbus, which also became vascularized. The vascularization seems quite characteristic. The vessels are all superficial and resemble an epaulette extending onto the cornea from the upper limbus, elevating its surface. The vascularized area does not stain. The lower border of the vascularized area is very sharply delimited; no isolated vessels grow into the infiltrate in front of the vascularized zone.

The patient first seen in the clinic of the Hospital of the University of Pennsylvania by Dr. Crandall was seen and discussed at one of the weekly conferences. The final conclusion reached by the staff members was that, because of the new vessels and the elevation of the surface of the cornea, neoplasm had definitely to be excluded as a diagnostic possibility.

Dr. Reese asked what resemblance these vessels had to the salmon patch of interstitial keratitis. The vessels in keratitis associated with lymphogranuloma venereum are superficial rather than deep as in interstitial keratitis.

Dr. Kelly asked about the effect of sulfonamide on the Frei test. It has none, and the Frei test remains positive for life. This explains why the Frei test can be confusing, and the diagnosis of lymphogranuloma venereum as the cause of any lesion must remain presumptive until the virus can be recovered.

The fourth patient presented was the most conclusive case. She had a positive Frei test, and, in addition, a very strongly positive complement-fixation reaction. A biopsy of the corneal lesion showed changes compatible with a diagnosis of lymphogranuloma venereum and now the virus inoculations seem to be showing positive results.

Finally, none of us has seen this corneal lesion in any patient not showing at least a positive Frei test for lymphogranuloma venereum. Even so, the diagnosis is presumptive at this point.

PIGMENTED NEVUS OF THE IRIS TREATED BY IRIDECTOMY

DR. JAMES S. SHIPMAN and DR. ROBB McDONALD presented a white woman, aged 59 years, who had had a spot on the iris of the left eye for as long as she could remember. Recently she had noticed that it had increased slightly in size. A tumor was noted in the lower temporal quadrant of the left iris, extending from about 1 mm. from the pupillary margin to the iridocorneal angle. The ciliary body was not involved. The tumor was removed by iridectomy, both operation and convalescence being uneventful. A diagnosis of leiomyoma was made by Dr. DeLong, and of nevus by Dr. A. B. Reese. Dr. Reese stated that this was a true nevus of the iris because nevus cells were present.

The tumor was completely removed at the time of operation. When the patient was last seen, vision in the left eye was correctable to 6/6.

Discussion. Dr. Perce DeLong said that the tumor under question had been submitted to many pathologists, and varied diagnoses were obtained. Some pathologists expressed belief that it was of a malignant nature. Others said that it was a nevus in an unusual location in the iris. Others agreed that it was a myoma.

Nevae usually grow from the anterior surface of the iris. This neoplasm arose from the substructure. It is quite unusual for a nevus to develop from this location.

The microscopic picture showed no special arrangement of cells; that is, there were no alveolar arrangements of cells commonly spoken of as nevoid bodies, nor did it contain epithelioid cells—both so

common in nevi. Instead, the cells were arranged in whorls. They were long, spindle cells and possessed many fibrils. Also, with the phosphotungstic-acid stain, the nuclei showed acidophilic reaction, a characteristic so common of myomas. For this reason Dr. DeLong felt that they were dealing with this type of neoplasm.

Dr. W. Zentmayer said that in one of two cases he had treated, the same difference of opinion existed among pathologists. The boy had had a fleshy looking growth of the iris, which was removed after the technique described in the case just reported.

The diagnosis of the first pathologist to examine the growth was leukosarcoma. He submitted it to a second pathologist who made a diagnosis of leiomyoma. Because of this difference of opinion, it was examined by a third pathologist who confirmed the diagnosis of the first pathologist. It was later studied by Colonel Ash who agreed with the second pathologist that it was a leiomyoma.

Dr. W. E. Fry said that he had had the opportunity to see this patient at the time of operation as well as to view the slides after the section was prepared. The case was somewhat similar to one which had been seen previously by him and by Dr. Adler and by Dr. Waite. The chief difference was that in the case he saw a contact glass was useful to determine a free angle.

After viewing the slides of the case presented by Dr. Shipman and Dr. McDonald, and after talking to both Dr. DeLong and Dr. Reese, he thought there were reasons for differing opinions. There could be some controversy in regard to the cells the slides showed. He believed this was a tumor in which the pigment-bearing cells were important, a malignant melanoma. Certainly the treatment of the patient was correct.

Dr. Burton Chance said that Dr. Zentmayer's case had certain aspects which

were quite like those in one of his patients. The tumor was removed in a manner similar to that described by Dr. McDonald. The man had received a number of different diagnoses. For five years, there had been a gradual, yet appreciable, growth of the tumor. It proved to be a mixed-cell sarcoma. The patient had insisted that the eye be removed immediately if the mass were malignant, and he had assumed the burden of the decision. With the assent of Drs. Posey and Madison Taylor, an otherwise perfectly healthy eye was excised. That was 20-odd years ago. Recently Dr. Chance had learned that the patient had been in perfect health ever since the operation.

Dr. Edmund B. Spaeth said that he had never seen a more beautiful photograph of an eye than the one showed by Dr. McDonald in his presentation. The photographs shown by Drs. Grove and Scheie in their presentations were also excellent. Presentations like these show the value of good photography in recording pathologic conditions.

Dr. James S. Shipman (closing) said that no less an authority than Duke-Elder states that at the present time our ideas as to the nature and classification of neurectodermal tumors are somewhat in a state of flux. It was not until 1910 that Verocay showed that these tumors were derived from a proliferation of the cells of the sheath of Schwann, indicating that they were of ectodermal origin.

Masson, 1926 to 1932, confirmed this opinion and more or less revolutionized all previous conceptions of neuroneoplasms. His researches were also confirmed by Stewart and Copeland, 1931; Foot, 1932; and others. Masson showed that cutaneous nevi arose from a neoplastic proliferation of the specialized end organs of the cutaneous nerves; namely, the Meissner corpuscle in the derma, and the Merkel-Ranvier cells, and the chromatophore, which are special types of

cells in the basal layers of the epithelium.

As a result of this finding, according to Duke-Elder, it appears that a number of tumors which used to be described in the literature as neurofibroma, plexiform neuroma, ganglionic neuroma, nevus, melanoma, and some types of sarcoma are neurogenic in origin, the fundamental cell of origin being the cell of Schwann.

According to Duke-Elder and Algernon Reese, nevi usually occur in the skin, conjunctiva, or at the junction of these two, and they are neuro-epithelial in origin, springing from the end apparatus of the sensory nerves which may be pigmented or nonpigmented.

The term melanoma seems to have been rather loosely used to describe a pigmented tumor in any part of the body and has no real value so far as indicating the origin or malignancy of the tumor. As has been pointed out in the presentation of this case, a pigmented tumor may be congenitally present in an iris for many years with no evidence of growth or increase in size until suddenly, for some unknown reason, it takes on the characteristics of malignancy as evidenced by its increase in size and extension into the angle of the anterior chamber, giving rise to some increase in ocular tension.

Certainly these signs should always make one feel very suspicious of malignancy and advise surgery, such as was done in this case, with the hope of removing the tumor in its entirety before it has invaded too far into the angle of the anterior chamber.

This case demonstrates the necessity of careful observation. Dr. Roth, who saw this patient and referred her to me, is to be congratulated for his acumen and for his judgment as to the time for surgical intervention. I am indebted to him for having referred this patient to me. I am more indebted to Dr. Zentmayer who confirmed our opinion as to the operation to be performed, and, more than that, for

having shown me just how to do this operation. I had the pleasure of being his assistant at a similar operation for just such a tumor of the iris about 19 years ago when I was a resident at the Wills Hospital.

This case has been presented as a preliminary report with the hope of stimulating some discussion and interest in tumors of the iris. Dr. McDonald and I hope to give a more complete report of this case at a later date when a more definite diagnosis has been agreed upon.

George F. J. Kelly,
Clerk.

PETER C. KRONFELD, *president*

CLINICAL PROGRAM

The Fundus Clinic at Cook County Hospital was presented. One hundred twenty-eight cases were shown, including 48 cases of vascular disorders and diabetic retinopathies, 14 cases of diseases of the optic-nerve head, 16 cases of specific retinal inflammatory lesions, and 18 cases of traumatic retinopathy. Nine cases of congenital fundus defects were also shown. The miscellaneous group included anemias and various blood dyscrasias with retinal pathology, as well as degenerative diseases of the retina.

GLAUCOMA FOLLOWING INTRACAPSULAR CATARACT OPERATIONS

DR. IRVING PUNTENNEY presented this subject, an abstract of which follows.

The incidence of glaucoma following extracapsular cataract varies. Most observers attribute this type of glaucoma to obstruction of the filtration angle. A comparison of the incidence of glaucoma fol-

lowing intracapsular cataract extractions shows an advantage in favor of the intracapsular extraction. Glaucoma, when it occurs, is often the end result of certain anatomic changes which have been brought about during the course of the operation. During the last two years 16 cases of glaucoma were studied and treated. The glaucoma followed Verhoeff intracapsular extractions. No mathematical figures can be given as to incidence, because the operations were not performed by the author. Analysis of the findings in uncomplicated extractions, however, reveals that approximately 65 percent of the patients had mushrooming of the vitreous, together with adhesions of the iris pillars to the corneal incision. This was usually associated with peripheral anterior synechiae. Delayed reformation of the anterior chamber occurred in approximately 33 percent of the cases, and an equal number had an iris collar. A study of the findings in the complicated extractions showed that all patients had vitreous in the anterior chamber, with adhesions of the iris and iris pillars to the cornea. Vitreous was adherent to the incision in 75 percent of patients. An iris collar was present in 25 percent, and iris prolapse occurred in 50 percent.

In general, most cases of glaucoma appeared to result from complications which occurred during or following delivery of the lens. It is possible that preoperative gonioscopy would have revealed peripheral anterior synechiae in a large number of these patients but, nevertheless, the precipitating factor seemed to be a shift in the position of the vitreous with mushrooming of the vitreous into the pupil, formation of anterior peripheral synechiae; adhesion between the iris columns and the cornea, adhesions between the vitreous and the cornea, the presence of an iris collar, and iris or vitreous prolapse.

Prevention of this type of secondary glaucoma depends upon four factors:

1. Ability of the operator to remove the lens without disturbing the vitreous.
2. Maintenance of the normal position of vitreous and iris.
3. Early restoration of the anterior chamber.
4. Elimination of an iris collar at the base of the iridectomy.

Discussion. Dr. Bertha A. Klien spoke of the emphasis placed by Dr. Puntteny on the prominent role of the vitreous in the pathogenesis of certain types of secondary glaucoma, and showed slides to illustrate some of the consequences of dislocation of the vitreous; that is, a herniation or prolapse into the anterior chamber or an incarceration into a penetrating scar. In many histologic preparations it is seen that, driven out of its normal habitat, the vitreous stimulates growth of certain cells of the tissues of its new surroundings. Dislocated vitreous may be covered gradually by corneal endothelium and new Descemet's membrane. It may be invaded by newly formed keratoblasts, which gradually solidify strands of vitreous by production of a substance similar to corneal parenchyma. Herniating or prolapsed vitreous may become rapidly anchored to the anterior surface of the iris by proliferation over it of the anterior border-layer endothelium, producing occasionally occlusion of the pupil or, in the case of a coexisting hemorrhage, by formation of a network of phagocytic wandering cells, which are deposited on its surface and gradually take on the appearance of fibroblasts.

Membranes formed by growth of such a variety of cells over and into the vitreous gradually shrink and may thus dislocate the vitreous still further and, in this way, perhaps exert traction upon portions of the ciliary body and produce a rise of tension by irritation of the ciliary processes.

It would be interesting to know

whether cyclodiathermy, which would be the operation of choice in such a condition, has proved to be especially successful in the treatment of secondary glaucoma after intracapsular lens extraction with damage to the vitreous.

Dr. William F. Moncreiff said that, for a round-pupil extraction, three corneoscleral sutures are of great value for the prevention of iris prolapse. Three mattress sutures are equivalent to six sutures, the wound is airtight and the anterior chamber can be immediately restored by filling it with an air bubble. Remnants of the air bubble may remain even for four days when the chamber has been well-filled. To avoid a shift in the position of the vitreous toward the wound, one must rely on retrobulbar injections to reduce the tension, avoidance of undue pressure on the eyeball, and, of course, the proper handling of the eye in all respects.

If the extraction is performed properly, the vitreous should not suffer any disturbance unless it is adherent to the lens, which is quite an uncommon condition. If fine sutures (0.004 or 6.0) are used, it will be found that one, two, or even three of the sutures when properly tied will cut out spontaneously on the corneal side within a week or two.

Dr. H. Saul Sugar emphasized the role of delayed reformation of the anterior chamber after extraction from the point-of-view of the gonioscope, by means of which the main factor of the formation of peripheral anterior synechiae has been observable. The vitreous is much more easily visualized gonioscopically when present in the chamber than one would imagine. Three things might be done to prevent glaucoma after cataract extraction, intracapsular or extracapsular. The round pupil has advantages particularly after intracapsular extraction. The use of eserine after operation keeps the angle of the anterior chamber open. It also has a

tendency to limit mushrooming of vitreous into the anterior chamber. In addition, corneoscleral sutures, plus filling the anterior chamber with bubbles of air, will aid in preventing this type of glaucoma.

Dr. Thomas D. Allen congratulated Dr. Puntenney on this excellent presentation, and felt that Dr. Klien's pictures were extraordinarily illuminating. He favored the use of the tonometer routinely in pre-operative study. Following instillation of homatropine, the use of the tonometer shows what dilation of the pupil has done to the eye and may show the possibility of glaucoma. He agreed on the advisability of waiting four days postoperatively before dressing the eye, and was quite convinced that much less postoperative glaucoma ensued if nature were allowed to take its course. Allen Greenwood said, some years ago, that anterior peripheral adhesions were due to incorrect use of the iris spatula in the postoperative toilet of the wound, that sometimes the back of the cornea was touched, and cells detached from Descemet's membrane, so that when the wound is closed, the iris is likely to become adherent. Insertion of air into the anterior chamber aids in replacing the iris, but Dr. Allen had the feeling that it might act as a foreign body.

Dr. Louis Bothman mentioned that often posterior synechiae occur after cataract operation without glaucoma. He wondered if Dr. Puntenney had any figures on the percentage of cases with glaucoma as compared with those which have synechiae without glaucoma.

Dr. Erwin E. Grossman recalled a study, made several years ago with Dr. Kronfeld, on the role of peripheral anterior synechiae in connection with glaucoma in aphakic cases. He felt that this study gave overwhelming evidence that the main cause of glaucoma was synechiae. In the cases of glaucoma without anterior synechiae, other causes were

found. Iritis was one of these causes.

In the cases of glaucoma with synechiae, the degree of glaucoma varied with the extent of the synechiae. Those cases that had glaucoma and no anterior synechiae seemed to respond very well to medication; whereas, those with extensive synechiae usually went on to surgery. More than 100 cases were included in the study.

Dr. Peter C. Kronfeld emphasized what Dr. Sugar and Dr. Grossmann said. The paper of Drs. Grossmann and Kronfeld (*American Academy of Ophthalmology and Otolaryngology*, 1941) showed a definite quantitative relationship between the extent of the anterior synechiae and the incidence and severity of glaucoma. Mushrooming of the vitreous into the anterior chamber is very common in aphakic eyes that do not have glaucoma. So far as Dr. Kronfeld could determine, corneoscleral sutures, which in principle consist of horizontal bites, should be named after Liegard and not after Kalt.

Dr. Irving Puntenney (closing) thanked Dr. Klien for her interesting and scholarly discussion. He was pleased to hear Dr. Moncreiff discuss the value of introducing air into the anterior chamber. He doubted that it acted as a foreign body and believed it could do no harm unless bacteria were introduced at the same time. Some men prefer to fill the syringe by sucking the air through moist gauze. The gauze is not a very efficient filter but may help to eliminate airborne bacteria.

It is necessary for the operator to be able to pull up the corneoscleral suture immediately after delivery of the lens. The technique described was used as a routine measure by Dr. Sanford Gifford, and many cases have been seen where speedy closure of the wound prevented vitreous loss.

Dr. Sugar's discussion was also appreciated, and the recent work of Sugar,

Kronfeld, and Gradle gives far more information on the subject than this paper. In response to Dr. Allen, the use of the tonometer should be stressed in recording intraocular pressure. It is a mistake to rely on tactile pressure and, if this is done, numerous glaucoma cases will not be diagnosed until field defects are present. It is not necessary to postpone routine eye dressings until the third or fourth day, unless the patient is apprehensive or there is a tendency to vitreous prolapse.

In answer to Dr. Bothman, no percentage can be given because gonioscopy was not done in all cases. However, the answer could be found in Dr. Kronfeld's work. The present study could not be carefully controlled; the findings herein discussed were readily seen not only with the gonioscope but also with the slitlamp.

MODIFICATION OF CATARACT DISCUSSION IN THE PRESCHOOL AGE GROUP

DR. WILLIAM F. MONCREIFF presented a paper on this subject which was published in this JOURNAL, December, 1946, volume 29, page 1513.

Discussion. Dr. James E. Lebensohn said that cataract before the age of six years, in what Dr. Moncreiff aptly terms the preschool group, can be considered a rather definite clinical division since all forms of cataract within this period characteristically have but a slightly differentiated and unresisting nucleus. He had observed some of Dr. Moncreiff's cases and was impressed by the results. The operative management has certain essential features:

1. Both eyes are operated on at the same sitting, if the condition is bilateral. Considering the slight risk involved this procedure is logical, as it minimizes hospitalization and promotes binocular vision.

2. Maximal mydriasis is maintained both before and after operation. In preoperative preparation it must be empha-

sized that only spastic mydriatics, such as 10-percent neosynephrin or 1- to 2-percent adrenalin, ensure full dilation of the pupil after loss of aqueous.

3. A wide opening of the capsule is accompanied by thorough fragmentation of the lens, avoiding, however, entry into the vitreous. Before spastic mydriatics were introduced in ocular surgery a similar method was practiced by Emmert in 1903, but because of increasing tension, a linear extraction regularly followed 24 hours later. Dr. Moncreiff reasons that the mechanics of such tension rise is associated with swollen lens substance trapped behind the iris and claims that, with his technique, this complication is adequately avoided.

4. Some aqueous is allowed to escape. This step, which was not permissible when atropine was the only mydriatic available, is physiologically sound, as the plasmoid aqueous which follows has a much higher content of proteolytic enzymes.

5. The last detail is irrigation of the anterior chamber to displace lenticular remnants from the capsular sac. In Morgagnian cataract, it is generally agreed that the milky-white fluid released by discission must be immediately evacuated. Does Dr. Moncreiff find his simple irrigation adequate in such cases, or must the discission wound be enlarged?

Few surgeons doubt the desirability of leaving the vitreous untouched. A coating of vitreous probably delays the absorption of lens matter. Even worse, after the discission needle penetrates the vitreous, a fine thread of the humor is almost invariably carried back to the wound. Infection may thus gain entrance, or later retinal detachment may follow from adhesion of vitreous to the corneal scar.

Dr. Moncreiff regards about one year as the youngest age suitable for operation because only then can the pupil of the eye be adequately dilated. In this he is in

practical agreement with Treacher Collins, who concluded, because of other structural features, that 10 months should be the minimal age.

Other details of the discission operation are worthy of attention. As Jackson maintained, it is safer to introduce the needle through the vascular limbus than through the clear cornea. As a further precaution, Herbert provides the wound with a covering by sliding the mobile conjunctiva to the point of puncture.

The surgery of soft cataracts has a long and dramatic history. Percival Pott, in 1775, was the first to propose laceration of the capsule as a distinctive method. About 30 years later, Saunders demonstrated its value in children, and his first report listed results on 14 persons born blind, one of whom was only two months old. In the years since, many patients have been acutely troubled by strings attached to the gift of sight, strings of vitreous, capsule, and lenticular debris. Dr. Moncreiff has tackled the problem with insight. His solution deserves the earnest consideration of all eye surgeons.

Dr. Glenn Harrison assumed that one inserts the irrigator through the same opening made by the knife-needle, and that the excess irrigating fluid would be expelled through this opening. Since the Ziegler knife-needle would have too long a blade to permit extensive manipulation inside the anterior chamber, does Dr. Moncreiff use a special knife-needle?

Dr. Peter C. Kronfeld said that the procedure advocated and practiced by Dr. Moncreiff may be described as maximum comminution of the lens by multiple incisions and dislodgement of the comminuted material into the anterior chamber by irrigation, both procedures being accomplished through a minimal opening in the eyeball wall.

Multiple, but not through-and-through incisions of the lens, were advocated by Straub. Intentional dislodgement of lens

material or, more specifically, the nucleus into the anterior chamber for the purpose of comminution, was practiced by Krueckmann. To use irrigation for this purpose is Dr. Moncreiff's original and valuable contribution.

While his series of cases is small, it is remarkable that he obtained optically satisfactory conditions with just one operation in six consecutive eyes. A larger series of cases will be necessary to prove that the dislodgement of the lens material from behind the iris into the anterior chamber constitutes an antiglaucomatous factor. In Dr. Falls's series, glaucoma occurred only in 8 percent of the operated eyes. There is no definite concept concerning the mechanism of such glaucomas. Even though most of the anterior chamber may be filled with fluffy lens matter in these cases, it is highly probable that the upper half of the angle is open and functioning. Thus, the concept of angle obstruction by lens material in the anterior chamber is probably too diagrammatic.

With regard to the work of the other authors mentioned by Dr. Moncreiff, Dr. Falls has said that the procedure at the University Hospital of the University of Michigan has been "rather deep incisions with rather deep vigorous stirring of the cortex of the lens."

It was Dr. Kronfeld's feeling that Ziegler's through-and-through needling operation had been abandoned, and that Dr. Moncreiff's criticism of the procedure was, therefore, rather unnecessary. Dr. E. B. Spaeth of Philadelphia, however, stated that there are still people who practice the Ziegler through-and-through needling operation. Dr. Spaeth, himself, considers it an obsolete and dangerous procedure (personal communication). Dr. Kronfeld was in agreement with Dr. Moncreiff and Dr. Spaeth in that (1) interference with the anterior vitreous should be avoided whenever possible and

(2) through-and-through incisions of the lens offer no advantages so far as comminution and absorption of the lens material is concerned. There is definite hope that Dr. Moncreiff's procedure will simplify the treatment of congenital cataract.

Dr. William F. Moncreiff (in closing) said, in reply to Dr. Harrison, that the knife-needle has a blade of which the sharp edge is practically straight, and is about 2.75 mm., or at most 3 mm., in length. Concerning escape of fluid, the shaft of the knife-needle should fill the incision and prevent loss of the anterior chamber during the entire dissection part of the procedure. Should aqueous be lost inadvertently, the chamber can be filled with the irrigator, and the knife-needle reinserted. Introduction of the tip of the irrigator two or three times is not likely to cause infection, and the routine use of penicillin as a prophylactic is neither desirable nor necessary.

It is common knowledge that lens substance absorbs most rapidly and completely when free in the anterior chamber, and free from any enclosure in the capsule. This is often seen, particularly in those cases where more than the usual amount of cortex remains after extracapsular extraction. It was seen more frequently in former times when irrigation of the anterior chamber was not routine in the extracapsular extraction. As Dr. Levensohn said, Percival Pott, almost 200 years ago, attempted in the dissection of congenital cataract to dislocate some of the lens substance into the anterior chamber with the knife needle. Obviously, the method described here was arrived at quite independently. As to the Ziegler operation, it is true that most good eye surgeons consider it dangerous, but it is currently used and endorsed, if not actually defended, by two very prominent eye surgeons, one of whom is still quite active.

Richard C. Gamble,
Secretary.
